Unfortunately, none of the aforementioned studies have determined whether developmental increases in WM are related to developmental increases in problem solving. There have been some studies that have investigated cross-sectional differences in WM and word problem solving as a function of age (e.g., Swan-

son, 1999), however, no studies that we are aware of have investigated longitudinally whether changes in children's WM are related to changes in problem solving. Thus, despite studies showing that WM and problem solving improve as a function of age in cross-sectional studies (Swanson, 1999, 2003), the influence of growth in WM on problem solving in children has not been established. Identifying such a growth effect would be extremely valuable because it would assist in providing a parsimonious account of the ability group differences in WM found across a number of problem solving measures.

This study addressed the questions as to whether growth in problem solving is related to growth in WM and whether these changes vary as a function of children with and without serious mathematical problem solving disabilities in three elementary age groups and two ability groups (children at risk and not at risk for serious math difficulties). On the basis of the aforementioned models, we considered three possibilities: (a) Growth in the relationship between WM and problem solving is primarily mediated by task-specific knowledge and skills in mathematical calculation; (b) growth in WM and problem solving is primarily mediated by the phonological loop; or (c) growth in the executive component of WM, independent of the phonological system and resources activated in LTM, contributes unique variance to problem solving.

For this study, we assessed LTM using performance on measures of arithmetic calculation and recognition of problem solving components. We assessed the phonological system using performance on measures of naming speed, phonological awareness, and STM. We assessed executive processing using performance on WM tasks modeled after the format of Daneman and Carpenter's (1980) measure. The WM tasks were assumed to capture at least two factors of executive processing: susceptibility to interference and manipulation of capacity in the coordination of both processing and storage (e.g., Oberauer, 2002; Whitney, Arnett, Driver, & Budd, 2001). The approach used in this study (as well as in others, e.g., Engle, Cantor, & Carullo, 1992), to assess whether a particular system plays the major role in mediating differences in performance, was to remove statistically that system's influence from the analysis. In this study, the influence of the phonological system (e.g., naming speed, STM) or LTM was partialled via a hierarchical regression analysis between problem solving and WM. We reasoned that if WM and problem solving are primarily mediated by a phonological system and/or LTM, then the predictions of problem solving performance by performance on WM measures should be nonsignificant when measures related to the phonological system and LTM are entered (partialled) in the analysis. However, if growth in the central executive system (executive processing) mediates the relationship between WM and problem solving, then the correlations between these two variables will remain significant when measures of phonological processing and LTM are partialled from the analysis.

In summary, three questions directed our study.

1. Do children identified at risk or not at risk for serious math problem solving difficulties in Wave 1 vary on measures of growth in problem solving and WM across the three testing waves?
2. Is growth in WM related to growth in word problem solving?
3. Which components of WM are related to predictions of problem solving accuracy and are those predictions mediated by individual differences in knowledge base, phonological processing, and/or a central executive system?

## Method

### Participants

For the first wave of data collection, 353 children from Grades 1, 2, and 3 from a Southern California public school district and private school district participated in this study. Final selection of participants was determined by parent approval for participation and achievement scores. Of the 353 children selected, 167 were boys and 186 were girls. Gender representation was not significantly different among the three age groups,  $\chi^2(2, N = 353) = 1.15, p > .05$ . Ethnic representation of the sample was 163 Anglo, 147 Hispanic, 25 African American, 14 Asian, and 4 other (e.g., Native American and Vietnamese). The mean socioeconomic status of the sample was primarily middle class on the basis of parent education or occupation. However, the sample varied from low-middle class to upper middle class. Means and standard deviations for the variables used in this study for all testing waves are shown in Appendix A, B, and C.

The second wave of the testing 1 year later included 320 children, and the third wave of testing 2 years later included 302 children. The attrition of children who dropped out of the study was due to moving out of the school district. A comparison was made among achievement and cognitive scores, socioeconomic status, and parent income or occupation between children retained and those not retained in the study. In the Wave 1 sample, 134 children (68 boys, 66 girls) were classified at risk for serious math problem solving difficulties (SMD), and 219 children (99 boys and 120 girls) were not at risk. No significant differences emerged between the two ability groups in terms of ethnicity,  $\chi^2(5, N = 353) = 8.67, p > .05$ , or gender,  $\chi^2(1, N = 353) = 0.06, p > .05$ . With regard to attrition, however, the at-risk sample was reduced from 134 to 116 (64 boys and 52 girls) children, and the not-at-risk sample was reduced from 219 to 186 (94 boys and 92 girls) children in Wave 3. The comparison of the two groups at Wave 3 indicated that no significant differences emerged between the risk groups in terms of gender,  $\chi^2(1, N = 302) = 0.61, p > .05$ . Differences did emerge, however, between the risk groups in terms of ethnicity,  $\chi^2(5, N = 302) = 12.03, p < .05$ . Ethnic representation of the SMD ( $n = 116$ ) sample in Wave 3 was 44 Anglo, 58 Hispanic, 7 African American, 4 Asian, and 3 other (e.g., Native American and Vietnamese). In contrast, ethnic representation for the children not at risk ( $n = 186$ ) was 96 Anglo, 63 Hispanic, 14 African American, 12 Asian, and 1 other (Vietnamese). Thus, the at-risk group in Wave 3 had lower Anglo representation (only 38% of the sample) than the children not at risk (52% of the sample).

No bias was detected in child attrition except that proportionally more Hispanic children dropped out of the study. However, we did not find that gender interacted significantly with the performance on dependent measures (all  $ps > .05$ ). Therefore, gender was not considered further in the analysis. The sample size and scores as a

function of age, ability group, and testing wave for each task are shown in Appendix A, B, and C.

### *Definition of Children at Risk for SMD*

In this study, children at risk for SMD were defined as having normal intelligence on the basis of a measure of fluid intelligence (in this case, the Raven Colored Progressive Matrices test score  $\geq 85$ ; Raven, 1976) but with a mean performance below the 25th percentile (standard score of 90 or scaled score of 8) on norm-referenced measures related to (a) solving orally presented word problems and (b) digit naming fluency. The 25th percentile cutoff score on standardized achievement measures has been commonly used to identify children at risk (e.g., Fletcher et al., 1989) and, therefore, was used in this study. Classification of children at risk for SMD and not at risk for serious math difficulties was based on norm-referenced measures of computation on the Arithmetic subtest of the Wechsler Intelligence Scale for Children—Third Edition (WISC-III; Psychological Corporation, 1991) and Digit Naming Speed from the Comprehensive Test of Phonological Processing (CTOPP, Wagner, Torgesen, & Rashotte, 2000) described in the following section. Children who yielded an average scaled score less than or equal to 8 (average of both measures) were considered at risk for SMD. A scaled score of 8 was equivalent to a standard score of 90 or a percentile score of 25.

Our rationale for the above classification procedures was as follows. There are no general agreed upon criteria for defining children at risk for serious math difficulties in problem solving, especially in Grade 1 when the instruction is only beginning to address mathematical operations and learning to read. In addition, few studies have focused on math word problem solving difficulties in younger children, let alone identifying possible definitional parameters of risk. Because first graders were used in our sample in Wave 1, it was necessary in our classification of children at risk to control for the demands placed on reading and writing. In addition, because our focus was on examining problem solving skill and not arithmetic calculation, per se, for classification purposes it was necessary to rely on different measures than studies that define math disabilities by computation skill (i.e., mental computation of word problems versus paper and pencil computation of arithmetic problems). In contrast to the literature on math disabilities or reading disabilities, we assumed that children with SMD may not have skill difficulties related to arithmetic calculation or reading, per se, but may nevertheless have serious difficulties in coordinating arithmetic and language processes to solve a problem. For example, children we identified at risk had reading and math norm-referenced scores in the average range (see Appendix A, B, and C). Further, because we were interested in the reasoning processes related to problem solving, we selected a reliable measure that presented questions orally and placed problems in a verbal context (e.g., "If I have an candy bar and divide it in half, how many pieces do I have?") rather than a written computational context ("1 + 1 = ?"). Thus, we utilized the oral presentation of story problems as a criterion measure of SMD. Therefore, children who scored at or below a scaled score of 8 were selected as SMD. No doubt, this measure has been found to be a "complex mix of abilities, including quantitative reasoning . . . (a narrow ability subsumed by fluid reasoning), working memory, verbal comprehension and knowledge . . . the first choice for

interpretation of Arithmetic should likely be as a measure of fluid reasoning" (Keith, Fine, Taub, Reynolds, & Kranzler, 2006, p. 118). This interpretation was also supported in the WISC-III version (Keith & Wittam, 1997).

In selecting children with SMD at Wave 1, we also focused on a child's verbal fluency with numbers during Wave 1 testing. We assumed that number naming speed may underlie children's ability to automatically access arithmetic facts and procedures (Bull, Johnston, & Roy, 1999; Geary, Brown, & Samaranayake, 1991). We assumed that children who have quicker access to numbers (i.e., faster number fluency) would be less at risk for mental computation difficulties than children less fluent in number naming. This seemed reasonable to us based on Hitch and McAuley's (1991) finding that children with math disabilities evidenced deficits in the speed of implicit counting. Further, speed of number naming has a parallel in the reading literature where both letter naming speed and phonological knowledge are assumed to underlie reading disabilities.

As will be shown in the Results section, the SMD classification of children in Wave 1 also differentiated children's performance in Waves 2 and 3. However, it is important to note that a small number of children ( $n = 15$ ; 13.16 % of the sample) did not stay at or below the 25th percentile (scale score of 8) across testing waves. Clearly, the problem solving and digit naming speed measure were not perfectly correlated and therefore the 25th percentile cutoff does not hold for both measures. For example, standard scores for the digit naming task were not stable over the three testing waves because children's scale score moved from an 8 in Wave 1 to a 9 in Wave 3 (42% of the sample). We reran the analysis comparing at-risk and not-at-risk groups using only the WISC-III Math subtest as an indicator of ability (cutoff scores at or less than a scale score of 8). However, because the pattern in performance across measures was comparable, we used both measures to classify children at risk for SMD during Wave 1 testing.

### *Tasks and Materials*

The battery of group and individually administered tasks is described below. Experimental tasks are described in more detail than published and standardized tasks. Tasks were divided into classification, criterion, and predictor variables. Cronbach's alpha reliability coefficients for the sample were calculated for all scores across all testing waves.

### *Classification Measures*

*Fluid intelligence.* Nonverbal intelligence was assessed by the Raven Colored Progressive Matrices test (Raven, 1976). We assumed that this measure tapped components of fluid intelligence in children (see Klauer, Willmes, & Phye, 2002; Stoner, 1982). Children were given a booklet with patterns displayed on each page, each pattern revealing a missing piece. For each pattern, six possible replacement pattern pieces were displayed. Children were required to circle the replacement piece that best completed the patterns. After the introduction of the first matrix, children completed their booklets at their own pace. Patterns progressively increased in difficulty. The dependent measure (range = 0–36) was the number of problems solved correctly, which yielded a standardized score ( $M = 100$ ,  $SD = 15$ ). The sample Cronbach's

alpha coefficients on scores for Waves 1, 2, and 3 on this task were .87, .89, and .90, respectively.

*Mental computation of word problems.* This task was taken from the Arithmetic subtest of the WISC-III (Psychological Corporation, 1991). Each word problem was orally presented and was solved without paper or pencil. The dependent measure was the number of problems correct, which yielded a scaled score ( $M = 10$ ,  $SD = 2$ ). The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 on this task were .74, .65, and .69, respectively.

*Digit naming speed.* The administration procedures followed those specified in the manual of the CTOPP (Wagner et al., 2000). For this task, the examiner presented participants with an array of 36 digits. Participants were required to name the digits as quickly as possible for each of two stimulus arrays containing 36 items, for a total of 72 items. The task administrator used a stopwatch to time participants on speed of naming. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 on this task were .92, .94, and .95, respectively.

### Criterion Variables

*Word problems—semantic structure varied.* The purpose of this experimental measure was to assess mental problem solving as a function of variations in the semantic structure of a word problem (see Swanson & Beebe-Frankenberger, 2004, for details on this measure). Children were orally presented a problem and were asked to calculate the answer in their head. The word problems were derived from the work of Riley, Greeno, and Heller (1983), Kintsch and Greeno (1985), and Fayol et al. (1987). There are four sets of questions. Eight questions within each set were ordered by the difficulty of responses. The dependent measure was the number of problems solved correctly. The total possible number of questions correct was 32. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for total scores on this task were .69, .54, and .65, respectively.

### Word Problem Solving Components

*Mathematical word problem solving processes.* This experimental test assessed a child's ability to retrieve the propositions or components related to word problems (see Swanson & Beebe-Frankenberger, 2004, for details on this measure). The components assessed were derived from the earlier work of Mayer (see Mayer & Hegarty, 1996, for a review). Four booklets were administered that each contained three word problems and a series of multiple-choice questions. Problems were four sentences in length and contained two-assignment propositions (one relation, one question) and an extraneous proposition related to the solution. To control for reading problems, an examiner orally read each problem and all multiple-choice response options as the students followed along. Questions assessed the students' ability to correctly (a) identify the question proposition of each story problem, (b) identify the numbers in the propositions of each story problem, (c) identify the goals in the assignment propositions of each story problem, (d) correctly identify the operation, and (e) correctly identify the algorithm for each story problem. At the end of each booklet students were read a series of true-false questions. All statements were related to the extraneous propositions for each

story problem within the booklet. The total score possible for propositions related to question, number, goal, operations, algorithms, and true-false questions was 12. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for total scores on this task were .97, .88, and .91, respectively.

### Arithmetic Calculation

*Arithmetic computation.* The Arithmetic subtest from the Wide Range Achievement Test—Third Edition (WRAT-III; Wilkinson, 1993) and the Wechsler Individual Achievement Test (WIAT; Psychological Corporation, 1992) were administered. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for the WRAT-III were .78, .84, and .71, respectively. For the WIAT, the sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .89, .86, and .76, respectively.

*Computation fluency.* This test was adapted from the Test of Computational Fluency (Fuchs, Fuchs, Eaton, Hamlett, & Karns, 2000). The adaptations required students to write answers within 2 min to 50 problems (25 on each page) of basic facts and algorithms. The basic facts and algorithms were problems matched to grade level (for Grades 1–5). The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for this task were .91, .97, and .98, respectively.

### Predictor Variables

#### Phonological Knowledge Measures

*Pseudoword reading tasks.* The Pseudoword subtest was administered from the Test of Word Reading Efficiency (TOWRE; Wagner & Torgesen, 1999). The subtest required oral reading of a list of 120 pseudowords of increasing difficulty. The dependent measure was the number of words read correctly in 45 s. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for this task were .94, .93, and .93, respectively.

*Phonological deletion.* The Elision subtest from the CTOPP (Wagner et al., 2000) was administered. The Elision subtest measures the ability to parse and synthesize phonemes. The child was asked to say a word and then say it again with a deleted part (e.g., "Say *popcorn*. Now say *popcorn* without saying *corn*"). The dependent measure was the number of items said correctly. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for this task were .91, .88, and .89, respectively.

#### Reading

*Word recognition.* Word recognition was assessed by the Reading subtest of the WRAT-III (Wilkinson, 1993). The task provided a list of words of increasing difficulty. The dependent measure was the number of words read correctly. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for this task were .91, .88, and .89, respectively.

*Real word reading efficiency tasks.* The Real Word Reading subtest was administered from the TOWRE (Wagner & Torgesen, 1999). The subtest required oral reading of a list of 120 real words of increasing difficulty. The dependent measure was the number of words read correctly in 45 s. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for this task were .88, .96, and .93, respectively.

*Reading comprehension.* Reading comprehension was assessed by the Passage Comprehension subtest from the Woodcock Reading Mastery Test—Revised (WRMT-R; Woodcock, 1998). The dependent measure was the number of questions answered correctly. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for this task were .93, .87, .84, respectively.

### *Naming Speed*

*Letter naming speed.* The administration procedures followed those specified in CTOPP. Participants were required to name the letters as quickly as possible for each of two stimulus arrays containing 36 letters, for a total of 72 letters. The dependent measure was the total time to name both arrays of letters. The correlation between arrays in Forms A and B was .90. The sample Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 for this task were .91, .87, and .81, respectively.

### *STM Measures*

Four measures of STM were administered: Forward and Backward Digit Span, Word Span, and Pseudoword Span. The digit subtest from the WISC-III was administered. The Forward Digit Span task required participants to recall and repeat in order sets of digits that were spoken by the examiner and that increased in number. The Backward Digit Span task from the WISC-III required participants to recall sets of digits in reverse order and was administered in the same manner as the Forward Digit Span task. The dependent measure was the highest set of items recalled in order (range = 0 to 6 for Backward Digit Span).<sup>1</sup> The Word Span and Pseudoword Span tasks were presented in the same manner as the Forward Digit Span measure. The Word Span task was previously used by Swanson, Ashbaker, and Lee (1996). The word stimuli are one- or two-syllable high-frequency words. Students are read lists of common but unrelated nouns and then are asked to recall the words. Word lists gradually increased in set size, from a minimum of two words to a maximum of eight. The Phonetic Memory task (Pseudoword Span task; Swanson & Berninger, 1995) uses strings of nonsense words (one syllable long), which are presented one at a time in sets of 2–6 nonwords. The dependent measure for all STM measures was the largest set of items retrieved in the correct serial order (range = 0–7). The Cronbach's alpha coefficients on scores for Waves 1, 2, and 3, respectively, scores for the Forward Digit Span were .78, .77, and .84; for the Backward Digit Span were .46, .62, and .48; for the Word Span were .70, .77, and .75; and for the Pseudoword Span were .58, .73, and .69.

### *WM Measures*

The WM tasks in this study required children to hold increasingly complex information in memory while responding to a question about the task. The questions served as distracters to item recall because they reflected the recognition of targeted and closely related nontargeted items. A question was asked for each set of items and the tasks were discontinued if the question was answered incorrectly or if all items within a set could not be remembered. For this study, WM tasks were divided into those identified in the literature as tapping executive processing (Listen-

ing Span, Updating, Sentence–Digit task, Semantic Association task) and those assumed to tap the visual–spatial system (Visual–Matrix task, Mapping–Direction task). The complete description of the administration and scoring of the tasks is reported in Swanson (1995). Task descriptions follow.

### *Executive Processing*

*Listening sentence span.* The children's adaptation (Swanson, 1992) of Daneman and Carpenter's (1980) Sentence Span Task was administered. This task required the presentation of groups of sentences, read aloud, for which children tried to simultaneously understand the sentence contents and to remember the last word of each sentence. The number of sentences in the group gradually increased from two to six. After each group was presented, the participant answered a question about a sentence and then was asked to recall the last word of each sentence. The dependent measure was the total number of correctly recalled word items up to the largest set of items (e.g., Set 1 contained two items, Set 2 contained three items, Set 3 contained four items, etc.) in which the process question was also answered correctly. Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .89, .89, and .83, respectively.

*Semantic association task.* The purpose of this task was to assess the participant's ability to organize sequences of words into abstract categories (Swanson, 1992, 1995). The participant was presented a set of words (one every 2 s per word), asked a discrimination question, and then asked to recall the words that "go together." For example, a child was first presented a list of the following words, *yellow, cake, red, cookies*, then was asked a discrimination question, "Did I say *red* or *orange*?" and then was asked to group the words by category (e.g., colors and food). In other words, the task required participants to transform information encoded serially into categories during the retrieval phase. The range of set difficulty was two categories with two words in each category in Set 1 and five categories of four words each in Set 7. Thus, the number of words in each set varied from 4 words in Set 1 to 20 words in Set 7. The dependent measure was the total number of correctly recalled words in which all items in the set were recalled and the process question for the set of words was answered correctly. Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .84, .91, and .93, respectively.

*Digit/sentence span.* This task assesses the child's ability to remember numerical information embedded in a short sentence (Swanson, 1992, 1995). For example, Item 3 states, "Suppose

<sup>1</sup> There is some debate as to whether the backward Digit Span test better captures WM than STM (Gathercole, Pickering, Ambridge, & Wearing, 2004). As suggested by Colom, Abad, et al. (2005) and Engle et al. (1999), the numbers reversed task is assumed to be mainly a short-term processing capacity measure. Colom, Flores-Mendoza, et al. (2005) found forward and backward span measures to be similar measures of STM storage (see p. 1010 for discussion). Further, as stated by Engle et al. (1999) "Rosen and Engle (1997) showed that the backward and forward word task displayed similar effects of phonological similarity ... suggesting that a simple transposition of order would be insufficient to move a task from the STM category to the WM category" (p. 314). In addition, Swanson, Mink, and Bocian (1999) found that with young children at risk for learning problems that both forward and backward digits loaded on the same factor as phonological processing (see Table 5).

somebody wanted to have you take them to the supermarket at 8-6-5-1 Elm Street." The numbers are presented at 2-s intervals, followed by a process question ("What was the name of the street?"). The dependent measure was the total number of correctly recalled digits, in which all items in the set were recalled (set size ranged from 2 to 14 digits) and the process question for the set of digits was answered correctly. Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .88, .91, and .93, respectively.

*Updating.* This experimental updating task was adapted from Morris and Jones (1990). For this task, a series of one-digit numbers was presented that varied in set lengths of nine, seven, five, or three. No digit appeared twice in the same set. The examiner stated that the list may be either long or short and the participant should only remember the last three numbers in the same order as presented. Each digit was presented at approximately 1-s intervals. The four practice trials used list lengths of three, five, seven, and nine digits each, in random order. It was stressed that some of the lists of digits would be short, so they should not ignore any items. That is, to recall the last three digits in an unknown ( $N = 3, 5, 7, 9$ ) series of digits, one must keep available the order of old information (previously presented digits), along with the order of newly presented digits. The dependent measure was the total number of lists correctly repeated (range = 0–16). Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .93, .89, and .89, respectively.

### *Visual-Spatial Sketchpad*

*Visual matrix task.* The purpose of this task was to assess the ability of participants to remember visual sequences within a matrix (Swanson, 1992, 1995). Participants were presented a series of dots in a matrix and were allowed 5 s to study the matrix. The matrix was then removed and participants were asked, "Are there any dots in the first column?" After answering the discriminating question (by circling *y* for yes or *n* for no), students were asked to draw the dots they remembered seeing in the corresponding boxes of their blank matrix response booklets. The task difficulty ranged from a matrix of 4 squares and 2 dots (Set 1) to a matrix of 45 squares and 12 dots (Set 11). The dependent measure was the total number of items correct up to the highest set, in which the process question was answered correctly. Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .78, .79, and .84, respectively.

*Mapping and directions.* This task required a child to remember a sequence of directions on a map (Swanson, 1992, 1995). The experimenter presented a street map with dots (stop lights) connected by lines and arrows, which illustrated the direction a bicycle would go to follow a route through the city. After the map was removed, the child was asked a process question ("Were there any stop lights [dots] on the first street [column]?"). The child was then presented a blank matrix, on which to draw the street directions (lines and arrows) and stop lights (dots). The task difficulty on this subtest ranged from 2 dots and 3 lines (Set 1) to 20 dots and 23 lines (Set 9). The dependent measure was the total number of items correct up to the highest set, in which the process question was answered correctly. Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .78, .79, and .84, respectively.

### *Fluency and Inhibition Measures*

Two tasks that we assume capture different aspects of controlled attention are fluency and random generation. Both tasks measure inhibition but emphasize different aspects. The fluency task requires individuals to spontaneously generate words in response to a category cue (e.g., generate animal names) or specific letter cue (generate words that begin with the letter *B*). These tasks have been associated with the executive processing that involves the controlled search-for words (e.g., see Rende, Ramsberger, & Miyake, 2002, for review). That is, participants are directed to activate needed information (animal names) while controlling the repetition of exemplars.

In the random generation procedure, on the other hand, participants are asked to keep track of the number of times that the items have been generated and to inhibit well-known sequences such as 1, 2, 3, 4 or a, b, c, d. This task differs somewhat from the fluency measure because participants must suppress rote or habitual responses (saying the letters of the alphabet in order) in order to quickly complete the task. Thus, during random generation the central executive system acts as a rate-limited filtering device that filters out habitual responses (see Towse, 1998, for a review of this measure).

*Categorical fluency.* This experimental measure was adapted from Harrison, Buxton, Husain, and Wise (2000). Children were given 60 s to generate as many names of animals as possible. Children were told, "I want to see how many animals you can name in a minute." The dependent measure was the number of different words correctly stated within 60 s. Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .76, .76, and .75, respectively.

*Letter fluency.* This experimental measure was adapted from Harrison et al. (2000). Children were given 60 s to generate as many words as possible beginning with the letter *B*. The dependent measure was the number of words correctly stated in 60 s. Cronbach's alpha coefficients on scores for Waves 1, 2, and 3 were .76, .76, and .75, respectively.

*Random generation of letters and numbers.* Each child was asked to write as quickly as possible numbers (or letters) first in sequential order to establish a baseline. Children were then asked to quickly write numbers (or letters) in a random nonsystematic order. Scoring included an index for randomness, information redundancy, and percentage of paired responses to assess the tendency of participants to suppress response repetitions. The measure of inhibition was calculated as the number of sequential letters or numbers divided by number of correctly unordered numbers or letters. It was our assumption that scores close to 1.0 would reflect a high and efficient ability to inhibit well-learned sequences. Cronbach's alpha for the Letter Generation task for Waves 1, 2, and 3 scores were .52, .69, and .63, respectively, and for the Number Generation task were .75, .68, and .69, respectively.

### *Procedure*

Five doctoral-level graduate students trained in test administration tested all participants in their schools in Waves 1, 2, and 3. One session of approximately 45–60 min was required for small group test administration and one session of 45–60 min for indi-

vidual administration for each wave. During the group testing session, data were obtained from the Raven Colored Progressive Matrices test, WIAT, WRAT-III, mathematical word problem solving process booklets, visual matrix test, and arithmetic calculation fluency. The remaining tasks were administered individually. We counterbalanced test administration to control for order effects. Task order was random across participants within each test administrator.

### *Statistical Method*

*Sequence of analysis.* The results are organized into five parts. First, we determined whether the memory tasks fit a three-factor model (central executive, phonological loop, visual-spatial sketchpad). Thus, we computed a confirmatory factor model to determine the adequacy of fit to the data. In addition, we converted tasks that were conceptually related to single latent variables to reduce the sample-task ratio and to simplify the analyses.

Second, we compared performance of children at risk and not at risk for SMD across the testing waves. Because some initial differences emerged between the groups on measures of the Raven Colored Progressive Matrices test, scores from this test were used as a covariate in the multivariate analysis of covariance (MANCOVA). This analysis addressed the question as to whether children identified at risk or not at risk for SMD in Wave 1 vary on measures of growth in problem solving and WM across the three testing waves.

Third, we tested for convergence across the three age cohorts. Convergence consists of testing whether cohort groups tested at the same age overlap in performance and the parameters of growth are equal for each of the cohort groups (see E. R. Anderson, 1993, for a review). This test was necessary because we were using a cohort-sequential design. The design assumes that the parameters of growth (levels, slopes, and error terms) are invariant across the three age groups. Therefore, it was necessary to establish convergence across the three cohorts (children who started testing at Grade 1 vs. children who started testing at Grade 2 vs. children who started testing at Grade 3). To accomplish this, we conducted structural equation modeling using EQS 6.0 (Bentler, 2005) to determine whether the latent measures were invariant across the samples.

Fourth, after factor invariance was tested across the latent measures, a growth curve analysis was conducted using hierarchical linear modeling (HLM; Bryk & Raudenbush, 1992; Singer, 2002). We sought to isolate the components of WM that best related to word problem solving. We report our procedures for using HLM modeling in the next section. Overall, this analysis addressed the question as to whether growth in WM was related to growth in word problem solving. We also addressed the question as to whether ability groups varied in their rate of growth. The HLM method overcomes some of the limitation of our MANOVA because it does not assume that an equal number of repeated observations are taken for each individual or that all individuals were measured at the same time point. The model also allowed us to use random effects to model the continuous functions of age. Further, the HLM procedure does not require that missing data be ignored and provides a valid means to addressing standard errors. In contrast to traditional MANOVA repeated measures in which significance is tested against the residual error, the test of fixed

effects in mixed models is tested against the appropriate error terms as determined by the model specification.

The final section of the results focused on Wave 1 predictions of Wave 3 word problem solving. In this analysis, we were not interested in growth per se or the multilevel structure of the data but rather in how much of the variability in problem solving in Wave 3 was accounted for in Wave 1 data. Because the explained proportion of variance is somewhat problematic in HLM analysis (e.g., a large number of variance components, negative  $R^2$  are possible, etc.; for discussion, see Snijders & Bosker, 1999, pp. 99–100), we used hierarchical regression models to simply isolate unique processes in Wave 1 that underlie word problem solving performance in Wave 3. This analysis allowed us to address the questions related to the three models (knowledge base, phonological system, central executive system) provided in the introduction. The key question addressed was whether performance related to three components of WM was related to predictions of problem solving accuracy and whether those predictions were mediated by individual differences in knowledge base, phonological processing, and/or executive processing.

A key assumption of this study is that partialing out the influence of STM from WM leaves residual variance related to controlled attention (Engle et al., 1999). Several studies have shown that WM and STM are distinct but highly related processes (e.g., see Heitz, Unsworth, & Engle, 2005, for a review). For example, Engle et al. (1999) investigated the relationship among measures of STM, WM, and fluid intelligence in adults. They found that STM and WM tasks loaded on two different factors. Although strong correlations emerged between the two factors ( $r = .70$ ), they found that a two-factor model fit the data better than a one-factor model. Further, they found that by statistically controlling the variance between WM and STM factors, the residual variance related to the WM factor was significantly correlated with measures of intelligence. That is, they found a strong link between the latent measures of WM, but not STM, to fluid intelligence (e.g., also see Conway, Cowan, Bunting, Theriault, & Minkoff, 2002). They interpreted their findings as suggesting that the residual variance related to the WM factor corresponded to controlled attention of the central executive system. Thus, in our regression analysis, we entered measures of STM and WM simultaneously into the regression model to determine whether unique variance related to WM would predict problem solving accuracy.

*HLM.* As mentioned previously, we examined growth in problem solving using a multilevel framework referred to as HLM. We applied growth modeling to the study of intraindividual change in problem solving and WM over the 3-year period via the PROC MIXED program in SAS 9.1 (SAS Institute, 2003). The HLM procedure allowed us to determine both the average rate of change and individual variability in change over time. Age was the variable that represented the passage of time in our growth model. Because we had only three data points at best, our focus was on linear change and, therefore, a curvilinear relationship could not be reliably calculated. To interpret the results, we centered age at 9.7 (mean age at Wave 3), so that intercepts reflected the expected performance at that age. (It is important to note that slope remains the same whether the mean age is centered at Wave 1, 2, or 3. However, the correlation between the intercept and slope does vary as a function of different centering.) Thus, we centered our data on

the mean age at Wave 3 because we were interested in the final status of individual children after 3 years of math instruction.

Our growth model yielded parameter estimates that defined both the overall trajectory of the sample (fixed effects) and deviations in the overall trajectories (random effects). The model is expressed as:

$$y_{ij} = \beta_0 + \beta_1(\text{age}_{ij}) + U_{0j} + U_{1j}(\text{age}_{ij}) + R_{ij},$$

where  $y_{ij}$  is the dependent variable (problem solving) measured at time  $i$  in child  $j$ ;  $\text{age}_{ij}$  is the child  $j$ 's age at time  $i$ ;  $\beta_0$  is the average intercept at 9.7;  $U_{0j}$  is the random intercept for child  $j$ ;  $U_{1j}$  is the random age slope for child  $j$ ; and  $R_{ij}$  is the residual for child  $j$  at time  $i$ . The between-children variance components,  $\tau^2_0 = \text{Var}(U_{0j})$  and  $\tau^2_1 = \text{Var}(U_{1j})$ , reflect individual differences in level (intercept) and rate of change (slope), respectively. Thus, we estimated the association between the outcome (problem solving) and repeated measures of age across the 3-year time periods. We refer to this as our *unconditional growth model*.

Clearly, performance on word problems will be influenced by instructional procedures in the math classroom. At the start of the study, children were nested within different classrooms that reflect different instructional approaches of the math teacher (for the majority of participants, math instruction was in the homeroom class). Our analyses of random effects for intercept and slope included children nested within classroom (or math teacher). Thus, we modified the random effects (between-children effects) as  $\tau^2_0 = \text{Var}(U_{0j}) \times (\text{Teacher or Math Class})$  and  $\tau^2_1 = \text{Var}(U_{1j}) \times (\text{Teacher or Class})$  to reflect individual differences in level (intercept) and rate of change (slope), respectively. Classroom (math teacher) placement was not a continuous variable across the testing waves. For our analysis we selected Wave 1 math teachers for the nesting effect on the basis of our results from our administration of a National Science Foundation (2000) National Survey of Science and Mathematics Education. This survey showed the greatest amount of variance in instructional approaches among teachers occurred during Wave 1 when compared with other testing waves. Thus, our random effects for intercept and slope were nested within classroom at Year 1 (thus, we had randomly varying intercepts and growth rates within classroom). It is also important to note that we initially used a three-level model (Level 1 effects within person, Level 2 effects between persons nested within classroom, Level 3 effects between classrooms; see Singer, 2002, p. 167 for an example of this three-level growth model). However, because the random effects at Level 3 were not significant and less than 2% of the variance, these random effects were dropped from the analysis. Our approach was consistent with the model specification steps outlined in Snijders and Bosker's study (1999; see pp. 94–97), which called for excluding nonsignificant random effects.

In summary, our HLM (Level 1 within person, Level 2 between persons nested within classroom) included random effects from intercepts and slopes for children nested within the classroom of the math teacher. We used this unconditional growth model to examine problem solving performance as a function of the intercept and slope. For the fixed effect, the intercept provided information on the average level of the dependent variable at age 9.7 and the average rate of change across individuals. For the random effects, the intercept represented the variation (variance) around the intercept and the slope indicated whether there was variance related to change overtime. Significant random effects indicated that children differed in the level (intercepts) and/or rate of change (slopes).

After establishing our unconditional growth model, we tested whether entering the components of WM into the model explained any statistically significant associations obtained related to fixed effects and random effects. This is referred to as a *conditional model*. When one or more predictors are introduced into the conditional model, the reductions in the magnitude of the various components when compared with the unconditional model are analogous to effect sizes (Snijders & Bosker, 2003). This is similar to the use of  $R^2$  in linear regression models. The primary distinction between a linear regression and HLM is that several  $R^2$  values are relevant to HLM because there are several variance components.

Reliability estimates for the HLM model are based on the random effects. The random effects of the unconditional model represent the proportion of variance in that effect (i.e., parameter specific rather than error variance). If the random effect is significant and has satisfactory reliability, then it is appropriate to test whether additional variables can explain some of the variance in the unconditional model. Specifically, the conditional model predicted that the level and slope of problem solving performance would be associated with WM performance. To evaluate the compatibility of the data with our conditional model, we tested the significance of the model change. This was done by comparing the differences between the deviance values (i.e., the likelihood value for the correspondence between model and data) from the unconditional and conditional growth model. These are chi-square values, and the number of parameters added for the conditional model serves as degrees of freedom. In general, models with lower deviance fit better than models with higher deviance values. The deviance test can be used to perform a formal chi-square test in order to compare a model that adds certain effects versus a model that excludes them. For the present study, a significantly lower deviance score for the conditional model indicated that the conditional model showed a better fit to the data than the unconditional model.

We also compared children at risk for SMD and not at risk on parameter estimates of the intercept and slope. Because our classification of risk for SMD occurred at Wave 1, we centered age at Wave 3. Ability group differences have been established at Wave 1 (Swanson & Beebe-Frankenberger, 2004) and therefore it would be more informative about the stability of ability group differences by centering performance at Wave 3. Within this hierarchical model, we conducted several analyses comparing the risk and nonrisk groups identified in Wave 1 on intercept and growth scores across an array of measures.

**Missingness.** Missing data occur in longitudinal designs whenever an intended measurement is not obtained. We experienced some loss in our sample in Year 3 ( $N = 353$  in Wave 1 and  $N = 302$  in Wave 3). HLM allows for an incomplete data set, using data from all participants with at least two points. We used maximum likelihood procedures to determine parameter estimates because the maximum likelihood estimation procedure has several advantages over other missing data techniques (see Peugh & Enders, 2004, for discussion).

## Results

The means and standard deviations for measures of intelligence, accuracy in recognizing problem solving components, problem solving solution accuracy, arithmetic calculation, phonological processing, reading, STM, WM, inhibition, and fluency for Waves 1, 2, and 3 are shown in Appendix A (starting with Wave 1 at

Grade 1), B (starting with Wave 1 at Grade 2), and C (starting with Wave 1 at Grade 3). Prior to testing our hypothesis, we considered normality of the data. Measures meet standard criteria for univariate normality with skewness for all measures less than 3 and kurtosis less than 4. Univariate outliers were defined as cases more than 3.5 standard deviations from the means. We examined multivariate outliers by calculating Mahalanobis'  $d^2$ . None of the cases were deemed outliers.

### *Confirmatory Factor Analysis and Data Reduction*

A critical assumption of this study was that three components were represented in our WM battery: executive processing, phonological loop, and visual-spatial sketchpad. In order to test this assumption, we ran a confirmatory factor analysis for Wave 1 data using the CALIS (Covariance Analysis and Linear Structural Equation) software program (SAS Institute, 2003) with the four WM tasks (Listening Span, Semantic Association, Digit-Sentence Span, Updating) loading on one factor, the four STM tasks (Forward Digit Span, Backward Digit Span, Pseudoword Span, Word Span) loading on a second factor, and the two visual WM tasks loading on a third factor (Visual Matrix, Mapping-Directions). The fit statistics were .91 for the comparative fit index (CFI; Bentler & Wu, 1995) and .05 for the root-mean-square residual error of approximation (Jöreskog & Sörbom, 1984), indicating a good fit to the data. All standardized parameters were significant at the .01 level. As we had no theoretical reasons for relying on a one-factor or two-factor model, the three-factor model was accepted as a good fit to the data for the total sample in Wave 1.

Because of the large number of variables, it was necessary to reduce two or more measures that were conceptually related to latent measures (factor scores). The weighting of these variables for Waves 1 and 2 are reported in Swanson's (2006) study. Task weightings for the latent measures used in regression analysis (to be discussed) are reported in Table 7. We used the SAS CALIS program to create factor scores for each set of measures with two or more variables. This procedure allowed us to calculate for each testing wave standardized beta weights. On the basis of the standardized loadings, we computed factor scores by multiplying the  $z$  score of the target variable by the factor loading weights for the total sample (see Nunnally & Bernstein, 1994, p. 518 for calculation procedures).<sup>2</sup> Factor scores were created for problem solving accuracy (WISC-III: Arithmetic; problem solving semantic structure varied), math calculation (WRAT: Math; WIAT: Math, Computation Fluency), word problem solving components (correctly identifying the word problem propositions-related questions, numerical information, goals, arithmetical operations, algorithm, and irrelevant information), reading (WRAT: Reading; WRMT: Reading Comprehension), phonological processing knowledge (TOWRE: Pseudowords, Elision), inhibition (random generation of letters and random generation of numbers), fluency (Phonological and Semantic Fluency), speed (rate naming speed of numbers and letters), phonological loop (Forward Digit, Backward Digit, Pseudoword Span, Real Word Span), visual-spatial sketchpad (Visual Matrix, Mapping/Directions), and executive processing (Listening Sentence Span, Digit/Sentence, Semantic Association, Updating).

### *Ability Group and Wave Comparisons*

Figure 1 shows the latent measures as mean  $z$  scores for each measure used in the subsequent analysis as a function of the three

cohorts and two ability groups across the three testing waves. The figure shows the starting points by age for three cohorts at Wave 1 and follows their performance across the three testing waves. The age range was from 6 to 10 (Grades 1–5). Figure 1 also shows children identified at risk for SMD and those not at risk within each cohort. All figures were scaled to show a range of 2.5 standard deviations above and below a mean  $z$  score of 0 based on Wave 1 performance.

As shown in Figure 1, measures that showed the greatest increase from ages 6 to 10 (Grades 1–5) were math calculation, reading, and random generation. Measures showing the smallest rate of change ( $< .25 SD$ ) were performance measures of fluency, phonological loop, and knowledge of word problem solving components. Across all measures, children identified at risk were lower in performance than those not at risk. It is important to note that problem solving from the WISC-III Arithmetic subtest and rapid naming of numbers from the CTOPP were used as classification variables and, therefore, it would be expected that differences emerged between these two groups in Wave 1 for problem solving and speed. However, we considered it an empirical question as to whether such differences at Wave 1 would be maintained in Wave 3.

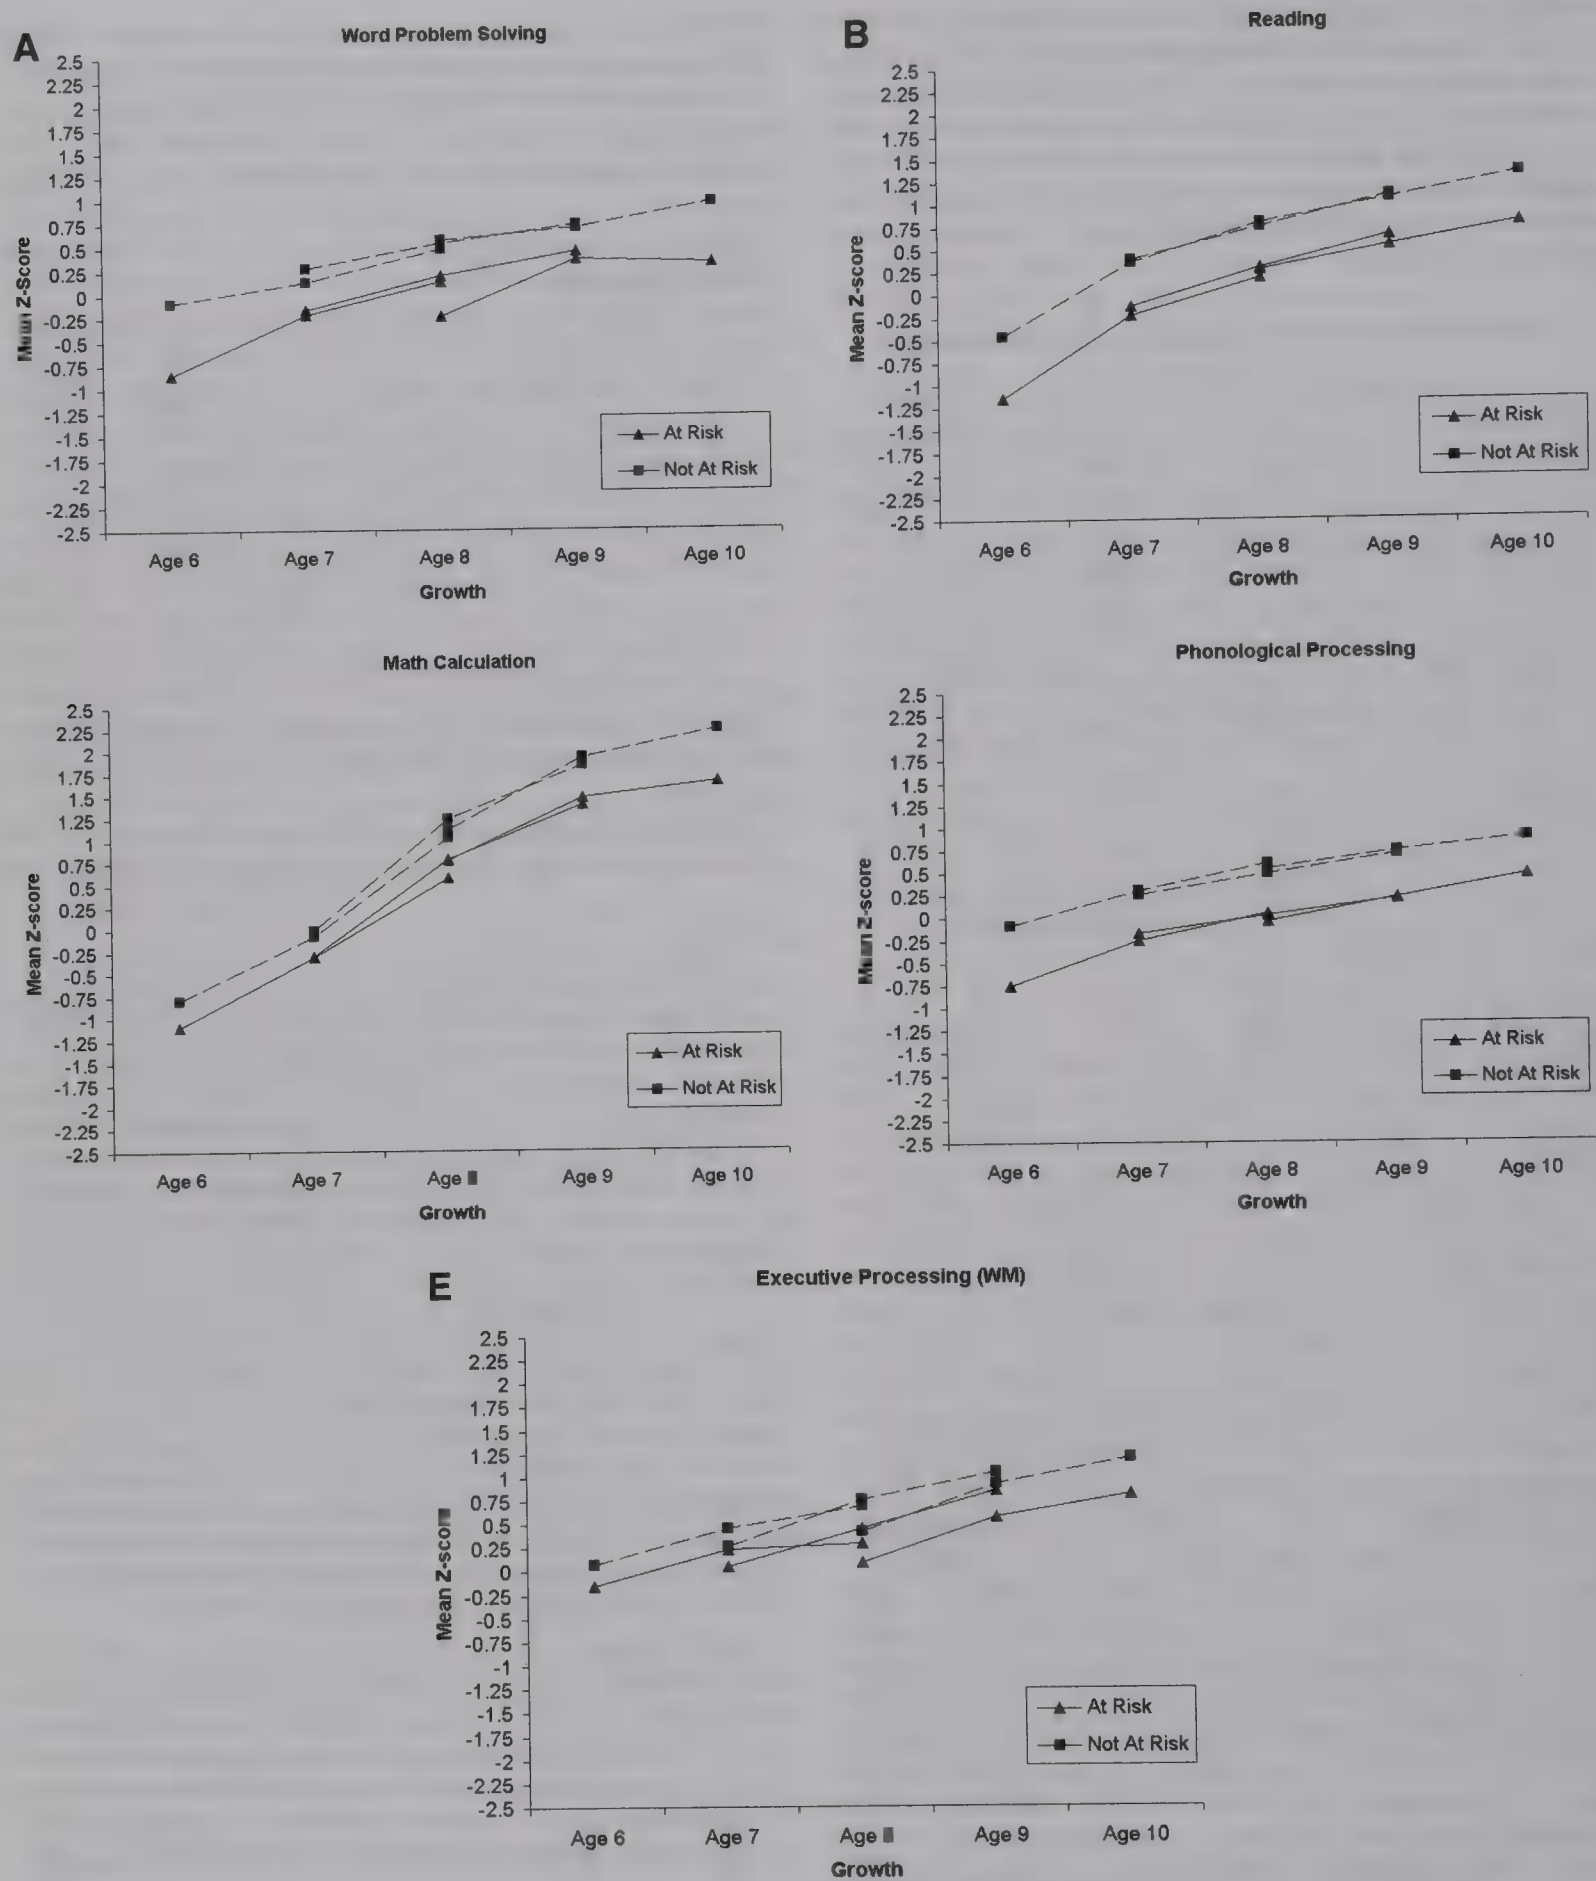

The primary question addressed in this part of the analysis was whether performance of children at risk for SMD varied from

<sup>2</sup> Consistent with other investigations of growth (e.g., Wilson et al., 2002), we converted raw scores to  $z$  scores. All measures were scaled to have a mean of 0 and standard deviation of 1 at Wave 1. Wave 2 and 3 measures were  $z$  scored on the basis of the means and standard deviations of Wave 1. It was necessary to scale to  $z$  scores across the total sample so that all parameters were on the same metric, enabling meaningful comparisons for both age and time (Waves 1, 2, and 3) (see McGraw & Jöreskog, 1971, for a discussion). In addition, because of the number of variables, we created factor scores. These scores were calculated for each of the three testing waves. This was done for measurement purposes (different variables have different weightings on a construct) and also for practical reasons: Some constructs (e.g., WM, STM) included several tasks. One reviewer questioned whether our scaling of items would best be served using an item response theory model. The item response theory framework posits a log linear, rather than a linear, model to describe the relationship between observed item responses and the level of the underlying latent trait,  $\theta$ . We agree with the reviewer's suggestion. However, as indicated by Nunnally and Bernstein (1994), for item response theory models "very large normative bases are required to implement all but the simplest and, therefore, sometimes unrealistic models using current estimation algorithms" (p. 396). In addition, as stated by Plewis (1996),

The feasibility of using vertical equating in the context of growth studies spanning a narrow range with different tests used at different ages has yet to be demonstrated. Certainly it is difficult to see how item response theory, which depends on fixing the mean and standard deviation of the ability distribution in order to estimate both item parameters . . . and an individual's ability, could be adapted to deal with growth without making arbitrary scaling assumptions. (p. 28)

Because we cannot address these issues with our current sample size (e.g., our sample is not large enough to establish anchor points), we attempted to place our values on the same measurement scale across the groups and investigate linear change. Converting data to  $z$  scores across the sample is appropriate when testing covariance structures (e.g., see Reise, Widaman, & Pugh, 1993, p. 557, for an example), as we have done in this study.

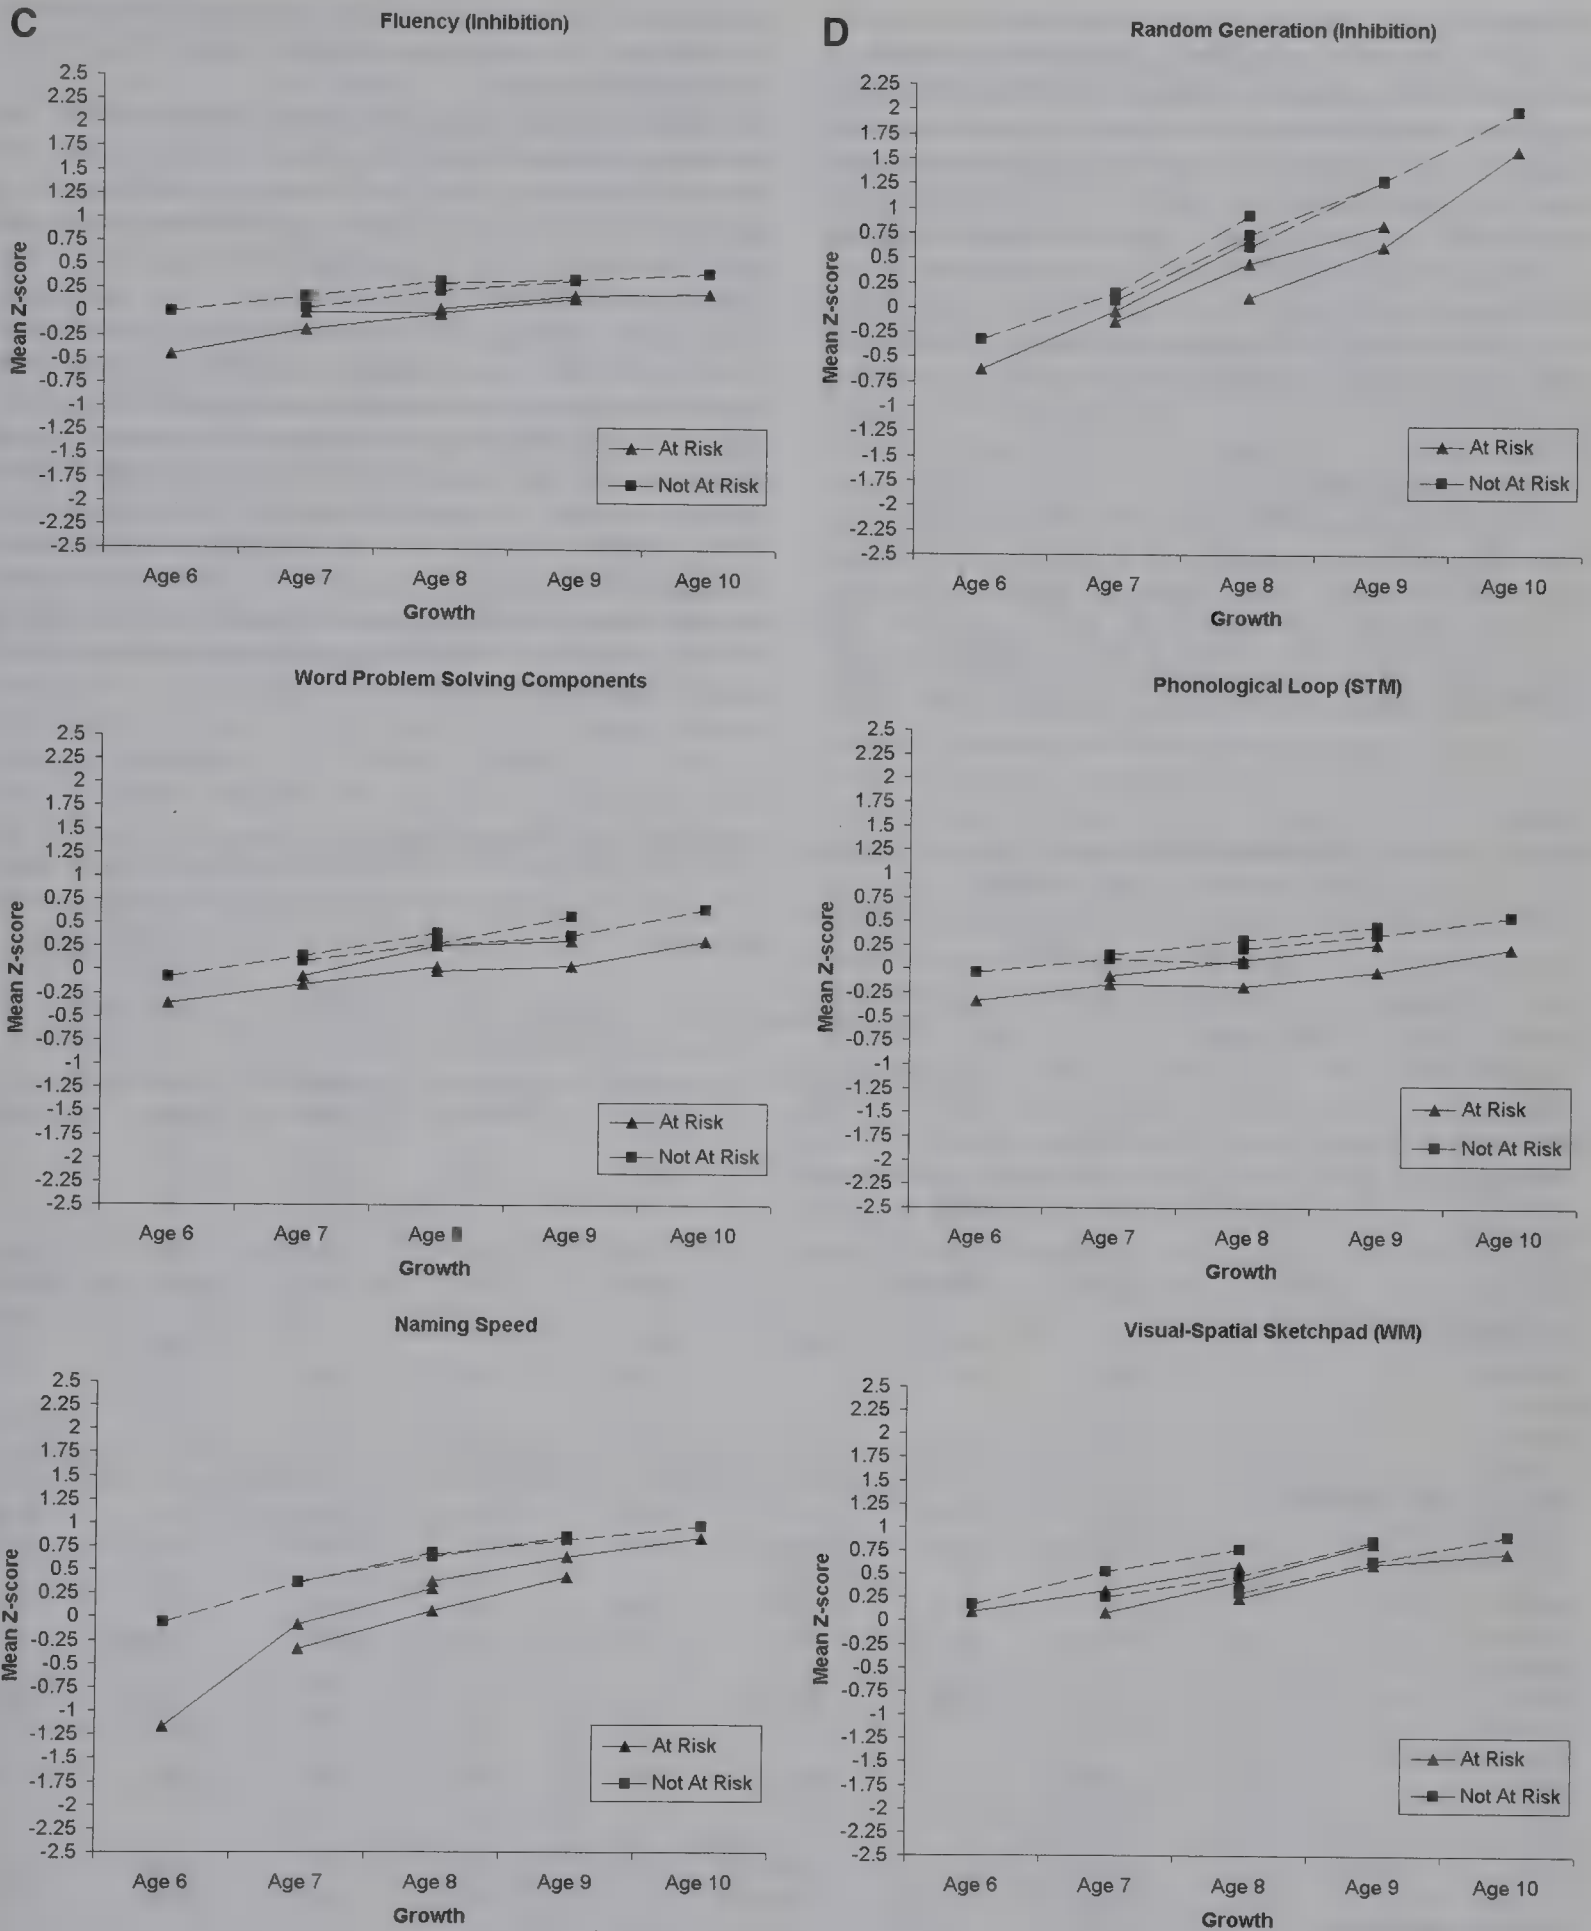

Figure 1 (opposite). Mean z scores for achievement and cognitive domains across testing waves as a function of age and ability group. STM = short-term memory; WM = working memory.

children not at risk on latent measures across testing waves. To address this question, we computed a 2 (risk group: children not at risk vs. SMD)  $\times$  11 (number of domains: problem solving accuracy, math calculation, word problem solving components, reading, phonological processing knowledge, inhibition, fluency, speed, phonological loop, visual-spatial sketchpad, and executive processing)  $\times$  3 (testing Waves 1, 2, and 3) repeated measures analysis of covariance (ANCOVA), with repeated measures on the last two factors. Although Raven scores were in the normal range for the at-risk group, an advantage was found for the not-at-risk group. Thus, Raven scores served as a covariate in the analysis. The covariate (Raven scores) was significant,  $F(1, 266) = 10.01$ ,  $MSE = 4.34$ ,  $p < .001$ , but the Ability Group  $\times$  Covariate interaction was not significant,  $F(1, 266) = 1.59$ ,  $p = .20$ , meeting the assumptions of a MANCOVA (homogeneity of the slopes). Thus, the covariate was judged to be reliable for the covariance analysis. Because there was a violation of sphericity (Mauchly's criterion reported probability  $< .0001$ ), we used the Greenhouse-Geisser and the Huynh-Feldt probability values. Because the samples of children not at risk and at risk for SMD

were matched on age, age was not considered as a covariate in this analysis. (The influence of age will be considered in the subsequent analyses.)

Omnibus  $F$  effects associated with the risk status, wave, and domain are reported below. The mean  $z$  scores of the latent measures are shown in Table 1 for Waves 1, 2, and 3. As shown in Table 1, the general pattern in the results was that children not at risk scored higher than those at risk for SMD, and scores were higher in testing Waves 2 and 3 than in Wave 1. Also provided in Table 1 is the difference in  $z$  scores between Wave 3 and Wave 1. As shown in Table 1, mean difference scores (Wave 3 minus Wave 1) greater than 1.0 standard deviation occurred for the measures of math calculation and inhibition. Although it is important to note that not all data can be used in this analysis (missing cells across waves are dropped), the results do show that differences between Wave 1 and Wave 3 were larger ( $z$  score differences  $> .40$ ) for the children not at risk on measures of math calculation and knowledge of problem solving components. In contrast, difference scores were larger for the at-risk group on measures of problem solving accuracy and naming speed.

Table 1  
Mean  $z$  Scores for Each Domain (Composite Score) as a Function of at Risk for Serious Math Difficulties (SMD;  $n=104$ ) and Not at Risk for Serious Math Difficulties (NSMD;  $n=166$ )

<sup>a</sup> Knowledge of problem solving components.

The repeated measures ANCOVA indicated that significant main effects emerged for ability group,  $\lambda = .50$ ,  $F(33, 235) = 6.92$ ,  $p < .0001$ ,  $\eta^2 = .50$ ; domain,  $\lambda = .77$ ,  $F(10, 258) = 7.62$ ,  $p < .0001$ ,  $\eta^2 = .23$ ; and testing wave,  $\lambda = .83$ ,  $F(2, 266) = 27.08$ ,  $p < .0001$ ,  $\eta^2 = .17$ . Significant interactions emerged for the Group  $\times$  Domain interaction,  $\lambda = .77$ ,  $F(11, 259) = 7.61$ ,  $p < .0001$ ,  $\eta^2 = .23$ ; the Domain  $\times$  Wave interaction,  $\lambda = .73$ ,  $F(11, 248) = 4.41$ ,  $p < .0001$ ,  $\eta^2 = .27$ ; the Ability Group  $\times$  Wave interaction,  $\lambda = .97$ ,  $F(2, 266) = 3.24$ ,  $p < .05$ ,  $\eta^2 = .03$ ; and the Ability Group  $\times$  Domain  $\times$  Wave interaction,  $\lambda = .66$ ,  $F(11, 248) = 6.19$ ,  $p < .001$ ,  $\eta^2 = .34$ .

A test of simple effects indicated that comparisons between at-risk and not-at-risk students were significant for each wave and domain. However, greater differences emerged between some domains than others. In general, a comparison of ability groups across domain (collapsed across time) indicated that the differences in favor of children not at risk, when compared with children at risk for SMD, were greater on all measures, except for the fluency and the storage components of WM (visual-spatial sketchpad and phonological loop). Further, when the difference scores between Wave 3 and Wave 1 served as a dependent measure (Wave 3 minus Wave 1), significant differences ( $ps < .01$ ) in ANCOVAs were found between ability groups for all measures except for the measures of STM (phonological loop), fluency, visual spatial WM (visual-spatial sketchpad), and inhibition ( $ps > .05$ ). As shown in Table 1, significant differences in scores emerged in favor of the nonrisk group on the remaining measures (all  $ps < .01$ ).

In summary, the general trend was that children not at risk scored higher than those at risk, and higher difference scores emerged for academic domains (e.g., math calculation) when compared with cognitive domains (e.g., inhibition).

### Convergence

A key assumption in growth modeling using a cohort sequent design is convergence. Convergence consists of testing whether cohort groups tested at the same age overlap in performance and

the parameters of growth (the levels, slopes, and error terms) are equal for each of the cohort groups (see E. R. Anderson, 1993, for a review). To address these assumptions, we used structural equation modeling (EQS 6.0; Bentler, 2005) to test whether the underlying linear growth processes (mean and variance of the slope and intercept factors) were invariant for the three cohort age groups (children in Wave 1 who started at Grade 1, 2, or 3). In structural equation modeling, it is possible to test the invariance (equality) on all parameter estimates across multiple groups. We evaluated the invariance of various sets of parameters across the three age groups. The present analysis determined whether the intercepts and slopes across all individuals depicted a common line. A statistical test of convergence was done to determine whether the parameters (the intercepts, slopes, and error terms) were equal for each of the three cohort groups. The baseline model reflected configural invariance that tested whether similar patterns (not necessarily identical) emerged between the three groups across the three testing waves. Configural invariance requires only that the number of factors and factor loading patterns be the same across the groups (Byrne, 2006, see p. 233). A goodness-of-fit statistic related to this multigroup parameterization should be indicative of a well-fitting model. A well-fitting model has CFI at or above .90 (Bentler, 2005). As shown in Table 2, the CFIs ranged from .95 to 1.00 for the configural or baseline model, indicating that groups share a common structure and pattern across all measures. As shown in Table 2, three models tested the equality (invariance) between groups on various parameters. We tested for invariance across the three samples (a) when all parameters (intercepts, slopes, and errors) were constrained to be equal (Model 1), (b) when the intercept for each sample that included the same grade levels (e.g., Grade 3 in all three samples, Grade 2 in two samples) was constrained to be equal (Model 2, slope or errors were not constrained to be equal across groups), and (c) when the intercept and slope for the same grades in each sample were constrained to be equal (Model 3, errors are not constrained to be equal). Generally, it is argued that invariance holds if goodness-of-fit (CFI) to the model (e.g., Model 1, 2, or 3) is adequate and if there is no

<sup>a</sup> Converged.

statistically significant difference from that of the configural model (Byrne, 2006). Although several authors consider Model 1 unrealistic (see Byrne, 2006, pp. 244–247), we found no statistical difference between the configural model (baseline model) and Model 1 for performance related to inhibition, visual–spatial sketchpad, or the phonological loop. For example, a statistical test between the phonological loop and the configural model was not significant,  $\Delta\chi^2(df = 14 [17 \text{ for Model 1}] - 3 [\text{for the configural model}]) = 21.21 (38.24-17.03), p > .05$ . As shown in Table 2, Model 2 showed convergence (invariance) for all cognitive and word problem solving measures (all  $\Delta\chi^2s > .05$ ). This finding indicated that the intercept values for overlapping ages were statistically comparable. We were unable to find convergence, however, on measures of reading and math calculation suggesting that other variables (e.g., instruction) influenced cohort effects.

HLM

As noted above, cross-group equivalencies were excellent on all measures, except two (reading and math). Thus, some sources of invariance were unaccounted for across the cohort groups. Instead of uncovering each invariant parameter across the age groups, however, we decided to center our results on age, using HLM procedures. This is because the majority of findings related to intercepts and slopes are conditional on age (see Mehta & West, 2000), and, therefore, it was not reasonable to ignore age differences. As stated by Mehta and West (2000), conventional SEM models based on sample means and covariance structures use an “inappropriate within person scaling of the time variables yielding incorrect estimates of some of the random effect and increased complexity of interpretation of age effects” (p. 24). To correct this, for our next analysis (consistent with Mehta & West, 2000) we scaled age with respect to a common origin across all individuals to reflect deviations from a common age.

Unconditional Model

Table 3 shows our individual growth modeling to the study of intraindividual change in problem solving over the 3-year period. We estimated individual-level trajectories as well as overall sample-level trajectories. Table 3 shows an unconditional mode, and Table 4 shows a conditional model. To interpret these tables, we first consider the unconditional model for the fixed effects in Table 3. The fixed effects model (which can be viewed as a one-way random effects analysis of variance model) provided the

estimates of the intercept (centered for the mean age at Wave 3) and growth. In this case, a mean *z* score of .58 was the predicted amount of solution accuracy at age 9.7 at Wave 3. The average unit of linear growth was .28. Hence, a 9.7-year-old ended Wave 3 with a *z* score of .58 and gained .28 units per testing session. Also shown are the *t* ratios (20.71 and 19.08) indicating that the parameter estimates were significantly greater than chance.

Also presented in Table 3 for the unconditional model are the model random effects for the total sample. The random effects include the intercept, slope, and within-child variance across testing waves. It is important to note that all students were exposed to variations in math instruction and, therefore, it was necessary to consider this variable in our calculation of random effects. We used as a representative variable the growth of students nested within classroom for Wave 1. Thus, our random effects (variance for intercept, slope) represented multiple observations of children (participants) nested within classrooms at Wave 1. As shown in Table 3, significant between-subjects variance emerged for the intercept (.18) and the slope (.03) estimates. Also included in the model was the within-person residual (.09). This estimate indicated that significant within-child variance emerged for problem solving accuracy across testing sessions.

Conditional Model-Group Effects

The conditional model in Table 4 shows a comparison of the two-risk groups identified at Wave 1 on problem solving accuracy. The difference between the two models is the addition of the classification (group) variable. For children at risk for SMD, the intercept (estimated *z* score for a child at 9.7 at the end of the study) for problem solving was .32, and linear growth rate was .41. These intercept and growth estimates were significantly better than chance. Likewise, for children not at risk, the intercept for word problem solving was .75 and the linear growth rate was .20. The intercept and linear growth estimates for the not-at-risk group were also significantly better than chance. In addition we determined whether the differences in estimated intercepts and growth rates varied significantly between the two groups. Ability group differences emerged in the estimated intercept values (.32 vs. .75),  $F(1, 927) = 62.93, p < .0001$  (note *df* denominator reflects estimated missing values), and the slope values (.41 vs. .20),  $F(1, 927) = 50.39, p < .0001$ . Thus, although ability group differences would be expected at Wave 1 (because at-risk groups were separated by problem solving accuracy and rapid digit naming), the results show

Table 3

that these differences remained at Wave 3. In addition, significant differences emerged between the two groups in linear growth, with the rate of growth higher in the at-risk than not-at-risk group. In summary, children not at risk had higher levels of performance at Wave 3 but lower linear growth estimates than children at risk.

Also presented in Table 4 for the conditional model are the model random effects for the total sample. When compared with the unconditional model, the estimated variances between subjects for the intercept (.14) and slope (.02) were significant. The random effects (estimated intercept variance between subjects and estimated variance within subjects) in the conditional model can be compared with the random effects in the unconditional model that has no ability group effects. Thus, one way of measuring how much of the variation in word problem solving accuracy was explained by creating ability group comparisons (in the conditional model) was to compute how much of the variance was reduced after comparing the variance estimates of the conditional model with those of the unconditional model. The percentage of reduction in between-subjects variance in the intercept related to the ability group conditional model was 22%:  $(.18 - .14)/.18 = .22 \times 100$ . We interpret this value by saying that 22% of explainable variation in child intercept values in Wave 3 is a function of the at-risk classification in Wave 1. (Note: the percentage reflected the fraction of variation that was explained. This is not the same as a traditional  $R^2$  statistic.) The explainable variation in slope was 33%:  $(.03 - .02)/.03$ .

Because of the number of estimates, Table 5 summarizes the fixed effects related to intercept and growth estimates for the ability groups across all measures. As shown in Table 5, the majority of estimates were significantly better than chance. The  $F$  ratios are shown comparing the ability groups on estimates of level performance and linear growth. Two important findings emerged. First, the level of performance (intercept values) was significantly lower for children at risk for SMD than children not at risk across all measures. Second, significant differences emerged in growth rates in favor of the not-at-risk group on all measures, except for the reading and phonological knowledge measures. No significant differences emerged between the two groups for growth rates on measures of fluency and STM (phonological loop).

### Conditional Model: WM Effects

One critical question that directed this study was whether growth in WM was related to growth in math problem solving accuracy. Table 6 shows the contribution of WM growth to problem solving accuracy. In this model, we tested whether the intercepts and slopes of problem solving were significantly related to the covariates. Covariates in this case were the intercept values and growth estimates for the three WM components. As shown in Table 6, a significant covariate effect was found for level of performance on all three components of WM. The estimated coefficients in Wave 3 for the phonological loop (STM; .14), executive processing (.09), and visual-spatial sketchpad (.10) were significantly related to problem solving. With respect to estimated growth rates, a significant effect occurred for the covariate of the phonological loop (−.05) and executive processing (−.10). The significant parameter estimate related to the phonological loop (−.05) indicated that a child who differed by a score of 1.0 with respect to performance on measures of the phonological loop had a growth rate that differed by −.05. Likewise, a child who differed by a score of 1.0 with respect to the executive system had a growth rate that differed by −.10.

When compared with the unconditional model in Table 3, the conditional model in Table 6 with WM components reduced variance related to between-children intercepts by 61%  $(.18 - .07)/.18$  and slopes by 66%  $(.03 - .01)/.03$ . We determined whether this conditional model provided a good fit to the data by calculating its deviance value (i.e., lack of correspondence between model and data). The log likelihood  $-2\ln(L)$  was 1,252.3 for the unconditional model and 954.7 for the conditional growth model. A significant chi-square indicated that the conditional model showed a better fit to the data than the unconditional model,  $\chi^2(6) = 297.6, p < .001$ .

In summary, ability group effects related to the level of performance in the final wave were higher for children not at risk across all measures when compared with children at risk for SMD. Significant growth differences in favor of the not-at-risk group emerged on all measures, except reading and phonological knowledge. No significant group differences emerged in growth rates on

measures of fluency and STM (phonological loop). An advantage in growth was found for the at-risk group on measures of phonological knowledge and reading. However, when the total sample was considered, growth in the phonological loop and the central executive component of WM were related to growth in problem solving accuracy. In addition, performance levels on all three components of WM were significantly related to problem solving accuracy.

### *Hierarchical Regression*

The final analysis determined those cognitive and achievement measures in Wave 1 that best predicted problem solving in Wave 3. These analyses specifically addressed the question as to which components of WM were predictive of problem solving accuracy and whether those predictions were mediated by individual differences in knowledge base, phonological processing, and/or a central executive system. Also included in this part of the analysis for the comparative purposes were the Wave 3 criterion measures of math calculation and knowledge of problem solving components. The estimates for these measures are shown in Table 7.

Prior to the regression analysis, we examined the correlations among the latent measures and the age variable. Correlations between scores for Waves 1 and 3 are shown in Table 8. The majority of

correlations greater than .20 in magnitude were significant at the .001 alpha level. As shown, all Wave 1 measures were significantly related to Wave 3 measures of problem solving accuracy, math calculation, and knowledge of the problem solving components.

An inspection of Table 8 revealed three important findings. (To interpret the results, we considered  $r_s > .40$  as substantial correlations.) First, problem solving accuracy in Wave 3 was substantially related to Wave 1 measures of reading, phonological knowledge, fluency, speed, phonological loop, and executive processing. Second, calculation skill and knowledge of problem solving components in Year 3 were strongly correlated with all Wave 1 measures except for inhibition. Finally, high correlations emerged between reading in Wave 1 and measures of math calculation and knowledge of problem solving components in Wave 3.

### *Predictions of Problem Solving*

We investigated whether the relationship between problem solving in Wave 3 and WM components in Wave 1 was maintained when blocks of variables such as knowledge base (e.g., calculation skill), phonological processing (STM, phonological knowledge), and age were entered into the regression analysis. For comparative purposes, we also considered in the analysis Wave 3 criterion

measures of math calculation ability and knowledge of problem solving components.

For our first set of analyses, we determined the amount of variance in problem solving performance in Wave 3 that was accounted for by WM components alone in Wave 1. For each model, we entered predictor variables from Wave 1 into the equation simultaneously, so that beta values reflected unique variance (the influence of all other variables was partialled out). For Model 1, we assumed that if scores related to STM (phonological loop) and visual-spatial sketchpad were partialled out in the regression analysis, then the residual variance related to WM could be attributed to the central executive system (e.g., Engle et al., 1999). As shown in Model 1 in Table 9, all components of WM contributed significant variance to the Wave 3 criterion measures. Performance related to the components of WM in Wave 1 contributed to approximately 36% of the variance to problem solving, 37% of the variance to arithmetic calculation, and 36% to problem solving component knowledge in Wave 3. As a follow-up to this model, we considered percentage of variance accounted for in the predictions when only the central executive component of WM was entered into the regression model. The central executive component of WM accounted for 27% of the variance for problem solving accuracy ( $R^2 = .27$ ),  $F(1, 291) = 110.06$ ,  $p < .001$ , 28% for math calculation ( $R^2 = .28$ ),  $F(1, 291) = 112.06$ ,  $p < .001$ , and 29% for problem solving knowledge ( $R^2 = .29$ ),  $F(1, 291) = 116.31$ ,  $p < .001$ . Thus, the contribution of the storage components of WM (phonological loop and visual-spatial sketchpad) in Model 1 increased the percentage accounted for by 9%, 9%, and 7%, respectively, when predicting problem solving accuracy, calculation accuracy, and problem solving knowledge.

In Model 2, we determined whether the contribution of the component scores related to WM in predicting the criterion measures were merely a function of chronological age at Wave 1. As shown in Table 9, all components of WM maintained significant

predictions of the criterion measures when age was partialled out in the analysis. The predictor variables in Model 2 for Wave 1 contributed approximately 38% of variance in word problem solving accuracy, 52% of the variance in math calculation, and 71% of the variance in problem solving component knowledge.

### *Role of Executive Processes*

As shown in Table 9, Model 3 assessed whether the contribution of WM to problem solving remained significant when cognitive

<sup>a</sup> Knowledge of problem solving components.

$r_s > .21, p < .0001$ .

variables (fluency, inhibition) assumed to underlie executive processing were entered into the analysis. That is, if the central executive system of WM was primarily related to inhibition and/or fluency, then entering these variables into the regression model should have partialled out the influence of the central executive component of WM. Model 3, when compared with Model 2, increased the percentage of variance accounted for by 2% in predicting word problem solving accuracy, by 6% in predicting calculation, and by 2% in predicting problem solving component knowledge. Wave 1 variables that contributed unique variance to all three-criterion measures were components of WM related to the central executive system. Chronological age contributed unique variance to calculation and problem solving component knowledge but not problem solving accuracy. In general, we did not find support for the notion that measures of fluency, speed, and inhibition eliminated the significant contribution of the central executive system to problem solving.

#### *Role of Phonological Processes*

Model 4, as shown in Table 9, determined whether the variables related to reading and phonological processing (e.g., reading, phonological knowledge) partialled out the influence of WM in predicting problem solving accuracy, math calculation, and knowledge of problem solving components. When compared with Model 3, Model 4 increased the percentage of variance accounted for by 4% for problem solving accuracy, by 11% for calculation, and by 5% for knowledge of problem solving components. The results showed that when compared with Model 3, the influence of naming speed was partialled out with the entry of reading variables into the equation. The only Wave 1 variable that contributed unique variance to all three-criterion measures was reading. Chronological age contributed unique variance to calculation and problem solving component knowledge. As found in Model 3, the central executive component of WM contributed unique variance to word problem solving accuracy and knowledge of problem solving components. In general, the results suggest that when compared with the previous models, the significant effects of the central

executive system of WM were eliminated only on the measure of calculation when measures of reading were entered into the regression analysis.

#### *Role of Knowledge Base*

Admittedly, we were surprised that measures of the central executive component of WM were not eliminated in predicting later performance of problem solving accuracy when measures of reading and executive processing activities (e.g., inhibition) were entered into the analysis. We reasoned that, perhaps, domain-specific knowledge in math calculation and general reasoning ability may account for the robust findings related to the WM measures. Thus, in a final model (Model 5) we entered Wave 3 scores related to math calculation ability and knowledge of problem solving components, and Wave 1 scores for fluid intelligence (Raven Colored Progressive Matrices Test) into the regression model. This model directly tested whether individual differences in children's knowledge base underlie the relationship between WM and problem solving. The results are shown in Table 10. The model determined whether domain-specific knowledge (math) and reasoning ability (fluid intelligence) would partial out the effects of WM in predicting problem solving accuracy. When compared with Model 4, the final model increased the percentage of variance accounted for by 5% when predicting problem solving accuracy. Predictor variables in Wave 3 that contributed significant variance to problem solving accuracy were math calculation and problem solving knowledge, and predictor variables in Wave 1 that contributed significant variance were fluid intelligence, visual-spatial sketchpad, and the central executive component of WM. Interestingly, when compared with Model 4, Model 5 completely eliminated the significant influence of reading on problem solving accuracy.

In summary, there were two important findings related to the hierarchical regression analysis. First, entering various cognitive variables attributed to executive processing (speed, fluency, and inhibition) as well as reading skill into the regression model did not eliminate the contribution of executive processing to predicting

problem solving accuracy or performance on the knowledge of problem solving components task. Second, performance on different components of WM predicted different criterion measures. The executive system and visual-spatial sketchpad were important predictors of problem solving accuracy, whereas performance related to the visual-spatial sketchpad predicted calculation, and the executive system predicted performance on the knowledge of problem solving components task.

### Discussion

The purpose of this study was to identify the cognitive processes in WM that predict mathematical problem solving performance in elementary school children who are at risk and not at risk for serious math difficulties. We determined whether WM was a valid construct in the predictions of problem solving and whether measures of WM predicted problem solving above and beyond children's performance on measures related to reading, phonological processing, computational knowledge, and domain-specific knowledge. We also determined whether growth in WM was related to growth in problem solving accuracy. Overall, our data provide substantial support for the notion that the capacity to store and process material in WM significantly constrains a child's

ability to problem solve during the elementary school years. Further, children identified at risk for problem solving difficulties in Wave 1 maintained their risk status on measures of problem solving and WM 2 years later. In the discussion that follows we review our findings related to WM and problem solving. We then discuss the implications of our findings for future research and practice.

### Testing of Three Models

We tested three models of WM and its influence on growth in problem solving. One model tests whether phonological processes (e.g., STM-phonological loop, phonological knowledge) play a major role in predicting performance in problem solving and whether the phonological system mediates the influence of executive processing (WM) on problem solving. Phonological processes in this study were related to latent measures of STM and phonological knowledge (measures of elision, pseudoword reading). The model follows logically from the reading literature that links phonological skills to new word learning (e.g., Baddeley et al., 1998), comprehension (Perfetti, 1985), and mental calculation (e.g., Logie, Gilhooly, & Wynn, 1994). The model assumes that poor problem solvers have deficits in the processing and storage of

phonological information that creates a bottleneck in the flow of information to higher levels of processing.

The second model suggests that domain-specific knowledge in LTM mediates individual differences in WM and problem solving. Measures of LTM in this study were related to calculation ability, reading, and knowledge of problem solving components. It has recently been argued that some of the functions of the central executive system are to access information from LTM (e.g., Baddeley & Logie, 1999), and, therefore, this model suggests that controlling for the activation of LTM (e.g., arithmetic calculation, knowledge of algorithms) would partial out the influence of WM on problem solving.

The final model suggests that problem solving performance relates to executive processing, independent of the influence of the phonological system and LTM. This assumption follows logically from the problem solving literature suggesting that abstract thinking, such as comprehension and reasoning, requires the coordination of several basic processes (e.g., Engle et al., 1999; Just, Carpenter, & Keller, 1996; Kyllonen & Christal, 1990). We assumed that measures of executive processing in this study were related to latent measures of WM, and measures assumed to reflect some of the activities of the central executive system were inhibition (random generation of letters and numbers) and activation of LTM (composite measures of reading, arithmetic calculation, knowledge of problem solving components). We also assumed based on the work of Engle et al. (1999) and others (e.g., Cowan, 1995) that after storage processes (phonological loop and visual-spatial) were partialled from the analysis that the residual variance related to WM captured a key process of the central executive system referred to as *controlled attention*. The results yield two clear findings in support of the third model. However, when interpreting these findings the reader needs to keep in mind that other processes not reflected in our latent measures may also play a role.

First, WM contributes unique variance to problem solving beyond what phonological processes (e.g., phonological knowledge), reading skill, inhibition, and processing speed contribute. The

results show that WM performance in Wave 1 contributed approximately 36% of the variance to problem solving accuracy in Wave 3 when entered by itself in the regression analysis. Thus, there is clear evidence that multiple systems of WM contribute important variance to problem solving performance beyond processes related to speed, phonological knowledge, and reading skill.

Second, WM performance predicted problem solving accuracy when the hierarchical regression analysis included measures of LTM. Measures of LTM in this study comprised the tasks related to reading, calculation, and knowledge of problem solving components. It has been argued that some of the functions of the central executive system include accessing information from LTM (e.g., Baddeley & Logie, 1999; Conway & Engle, 1994). Our results suggest, however, that although WM tasks draw information from LTM (e.g., knowledge of components related to problem solving), it may be the controlled attention (monitoring of attention) component of WM that plays a more important role in mathematical problem solving growth. The results clearly show in the final model (see Table 10, Model 5) that neither knowledge of problem solving components nor calculation ability partialled out the significant influence of WM in predicting mathematical problem solving accuracy. We will now address the three specific questions that directed our study.

1. Do children identified at risk or not at risk in Wave 1 vary on measures of growth in problem solving and WM across the testing waves?

To answer this question, we estimated intercept values in Wave 3 and the rate of growth across testing waves on measures of problem solving and WM. The growth curve analysis showed that ability group differences in problem solving emerged for the estimated intercept values at Wave 3. Thus, although ability group differences would be expected at Wave 1, the results showed that these differences were sustained at Wave 3. Although we were uncertain whether improvement in reading would mitigate any word problem solving differences in subsequent years, children at risk for SMD in Wave 1 were also at risk in Wave 3. In addition, significant differences emerged between the two groups in linear growth, with the at-risk group showing a lower growth rate when compared with the not-at-risk group. We also found that the intercept and linear growth parameters were significantly different between children at risk for SMD and not at risk on measures of math calculation and the executive component of WM. Children at risk for SMD had lower intercepts and smaller growth rates than children not at risk. Interestingly, no differences were found between the ability groups on growth estimates for performance on measures of the phonological loop and fluency.

We also compared the two groups across a broad array of achievement and cognitive measures. The general pattern in the repeated measures ANCOVA for the intact sample across all three waves was that the comparisons between at-risk and not-at-risk students were significant at each wave and for each academic and cognitive domain. However, greater differences emerged between ability groups for some domains than others. A comparison of groups across achievement and cognitive domains (collapsed across time) indicated that greater group differences in favor of children not at risk emerged on measures of problem solving accuracy, math calculation, reading, and speed when compared

with the cognitive variables (fluency, inhibition, and memory components; e.g., phonological loop) and knowledge of problem solving components. The general trend was that children not at risk scored higher than those at risk for SMD, and higher difference scores emerged for academic domains (e.g., reading, math calculation) than cognitive domains.

2. Is growth in WM related to growth in word problem solving accuracy?

Our multilevel analysis showed a positive effect for growth in WM and problem solving accuracy. The general findings of the growth analysis were that ability group effects related to intercepts and growth parameters emerged for measures of problem solving. Children at risk for SMD showed lower levels of performance and less linear growth rate than children not at risk. When the total sample was analyzed, however, another important finding was that all intercept values related to components of WM (phonological loop, visual-spatial sketchpad, and central executive) were significantly related to problem solving. A significant relationship was found for the level of performance on all three WM components to problem solving accuracy. However, only the linear growth in the phonological loop and executive processing was related to word problem solving.

No doubt, it could be argued that growth rates in problem solving are merely a function of classroom instruction. We addressed this issue by comparing an unconditional and conditional model that included growth of the students nested within classroom with and without the inclusion of WM. The conditional model that included WM reduced the influence of classroom (teacher) variance on between-children intercepts by 61% and between-children growth by 66%. Thus, we found that a large percentage of the variance related to participant performance nested within classroom instruction on problem solving could be accounted for by individual differences in WM.

3. Which components of WM were predictive of problem solving accuracy and are those predictions mediated by individual differences in knowledge base, phonological processing, and/or the central executive system?

We tested this question by utilizing a hierarchical regression analysis, in which variables related to WM, cognitive processing (speed, inhibition, fluency), and achievement (e.g., reading, phonological knowledge) in Wave 1 were systematically entered into the regression equation to predict problem solving in Wave 3. There were two important findings.

First, the results show that the executive component of WM contributes unique variance to problem solving accuracy beyond what phonological processes (e.g., STM, phonological knowledge) contribute. The results show that the executive component of WM performance in Year 1 contributes approximately 27% of the variance to problem solving accuracy in Wave 3 when entered by itself in the regression analysis.

Second, the executive component of WM performance contributes unique variance to problem solving accuracy even when the hierarchical regression includes measures of LTM. Our results suggest, however, that although WM tasks draw information from LTM (e.g., knowledge of components related to problem solving),

it may be the monitoring of the components in WM system (e.g., manipulation of information) and storage of visual-spatial information that play a more important role in predicting later performance on mathematical problem solving measures. However, our results must be clarified because we have merely partialled out the influence of the amount of knowledge available. A distinction must be drawn between the amount of WM resources available to produce activation and the amount of knowledge that can be activated. Thus, in our regression analysis we assessed the quality of information available, not the capacity to activate LTM knowledge. The results merely show that both knowledge of problem solving components and calculation ability in Wave 3 did not partial out the significant influence of WM in Wave 1 in predicting word problem solving accuracy in Wave 3.

As a parallel to predicting word problem solving accuracy, we also considered predictions related to mathematical computation. In terms of math calculation in Wave 3, the best Wave 1 predictors were reading, chronological age, and the visual-spatial storage (sketchpad) component of WM. Thus, in contrast to the important role that the executive component of WM plays in problem solving accuracy, it appears that performance in the visual-spatial sketchpad also predicts math calculation. The visual-spatial sketchpad is specialized for the processing and storage of visual material, spatial material, or both and for linguistic information that can be recoded into visual forms (see Baddeley, 1986, for a review). Our findings are consistent with studies (Gathercole & Pickering, 2000a, 2000b) finding that visual-spatial WM abilities, as well as measures of executive processing, were associated with attainment levels on a national curriculum for children ages 6 to 7 years. Children who showed marked deficits in curriculum attainment also showed marked deficits in visual-spatial WM. Thus, there is a strong relationship between measures of the visual-spatial sketchpad and academic performance in the younger grades.

### *Comparisons With Related Studies*

Not all studies have found a significant relationship between WM and problem solving. For example, Fuchs et al. (2006) studied the cognitive correlates of arithmetic computation and arithmetic word problem ability of third graders. Predictor variables were language, nonverbal problem solving, concept formation, processing speed, long-term memory, WM, phonological decoding, and sight word reading efficiency. Word problem accuracy was best predicted by concept formation and sight word efficiency. The only significant cognitive predictors of arithmetic were phonological decoding and processing speed. Likewise, earlier work by Fuchs et al. (2005) showed that phonological processing was a unique determinant of the development of arithmetic skills in first graders. The study by Hecht, Close, and Santisi (2003) also demonstrated that phonological processing almost completely accounted for the association between reading and computational skill in older children. In contrast, Lee, Swee-Fong, Ee-Lyn, and Zee-Ying (2004) assessed the performance of 10-year-olds on measures of word problems, WM, intelligence, and reading ability. They found that children who had greater storage and greater central executive system capacities related to WM measures were better able to solve mathematical problems. At the same time they found that children with higher IQs, reading proficiencies, and vocabularies, performed better on mathematical problems. Further,

although WM was found to be related to problem solving, WM did not contribute important variance to problem solving accuracy after measures of reading were entered into the regression analysis. This finding replicated an earlier finding from the study by Swanson et al. (1993), who found that reading comprehension performance superseded any unique contributions made by WM measures to problem solving (also see Kail & Hall, 1999, for a similar finding). These findings are in contrast to other researchers (e.g., De Beni, Palladino, Pazzaglia, & Cornoldi, 1998; Passolunghi, Cornoldi, & De Liberto, 2001), who have shown that when controlling for vocabulary and reading, poor problem solvers exhibit lower WM scores (as indexed by their poorer inhibitory abilities) than do good problem solvers.

Thus, there is some confusion in the literature about the role of WM in problem solving. To examine these issues, we give attention to the recent study by Fuchs et al. (2006). As stated, Fuchs et al. (2006) failed to find that WM predicted word problems accuracy, and this finding varies considerably from our findings. There are three major distinctions between the Fuchs et al. (2006) study and our study. First, there were variations in WM measures. Fuchs et al. (2006) primarily relied on two WM measures. One was the backward span that some consider a STM rather than WM measure (Colom, Abad, et al., 2005; Colom, Flores-Mendoza, et al., 2005; also see Footnote 1). In contrast, our study used a comprehensive battery of WM measures. Second, participants in the Fuchs et al. (2006) study were primarily sampled from Title 1 schools and identified on the basis of the performance on a nonstandardized test of computational fluency. Further, approximately 60% of their sample received subsidized lunch. In contrast, the present study sample of children comes from mostly middle-class or upper middle-class homes who were selected on a standardized measure of problem solving. In addition, it is important to note that the at-risk sample in the present study included students who were within the average range in arithmetic and reading skills. In contrast to the Fuchs et al. (2006) study that defined risk as the ability to calculate, our study defined risk as the ability to problem solve and name numbers quickly. Finally, as indicated by one reviewer, our results when compared with the work of Fuchs et al. (2006) were primarily due to methodology differences. For example, variations emerged in the criterion measure. In the Fuchs et al. (2006) study, word problems were presented as text and students had to process text. Children were allowed 3 s to respond after hearing the problem but could reread the passages if necessary. This activity would certainly lessen the demands on WM capacity because children can reread the sentence. In contrast, we read the problem to the students and students were able to focus on the problem being read while maintaining information in WM. Therefore, the reviewer was not surprised that reading played a minimal role in our study and was important in the Fuchs et al. (2006) study. Further, as indicated by the reviewer, the presentation of word problems in text in the Fuchs et al. (2006) study may be more ecologically valid than ours. We would argue that it is equally valid to problem solve without recourse to text—thinking on your feet as it were. Everyday problems are not always presented in text and it may be ecologically valid to also teach problem solving without having to rely on printed text. As indicated by an anonymous reviewer of this article, we could argue that we have a purer

measure of word problem solving because reading was not required.

On the issues of reading, some studies have argued that reading proficiency mediates the relationship between WM and problem solving. For example, Lee et al. (2004) showed that literacy measures provided greater contribution than measures related to the central executive system to word problem solving ability in children. Although WM was significantly related to word problem solving ability, its variance was significantly reduced when the influence of reading was partialled out. Further, they found that the storage component of WM, primarily the phonological loop and the visual-spatial sketchpad, did not contribute directly to mathematical performance.

Similar to Lee et al. (2004), as well as Fuchs et al.'s (2006) study, we found that reading was an important predictor of calculation. However, the contribution of WM to problem solving in our study was larger than that of reading. No doubt, the weak association of reading to problem solving in Model 5 (see Table 9) could be explained by the fact that all problems used in the current study were read to the students; consequently, reading was weakened as a possible mediating variable. We argue, however, that if children are unable to understand and decode a question, further processing is unlikely to lead to a correct solution. Therefore, reading abilities may account for the similarities and differences in the findings across studies.

In addition, there are other studies that clearly show that reading or reading-related processes do not directly mediate the influence of WM on problem solving. For example, Swanson and Sachse-Lee (2001) found with 12-year-old math-disabled and chronologically age-matched peers that phonological processing, WM (executive component), and visual WM contributed unique variance to problem solving accuracy. Thus, they did not find support that reading ability or literacy processes mediated the role of WM in the problem solving accuracy. In a follow-up study, Swanson (2004) compared two age groups (7 and 11) on WM and problem solving measures. This study found that regardless of age, WM predicted problem solving accuracy in word problems independent of measures of problem representation, knowledge of operations and algorithms, phonological processing, fluid intelligence, and achievement in reading and math. Further, the results suggest that a central executive system underlies age-related improvements in word problem solving accuracy.

In general, we argue that the correct calculation of numbers presented on paper requires some minimum threshold of reading ability. A lack of control for this confound may lead to attributing difficulties in math to the same cognitive processes (phonological process) as reading. In addition, children who read at a certain threshold (e.g., above the 25th percentile in word identification) may fail to be adequately diagnosed as having potential difficulties in mathematical problem solving. In order to circumvent these problems, we feel it is necessary to identify processes in children at risk for SMD that are distinct from the processes related to reading. Our results clearly show that children at risk for SMD on a nonreading measure but whose performance is in the average range on measures of fluid intelligence, reading skill, and math calculation skill are deficient on measures of WM when compared with children not at risk for problem solving.

### Implications

In general, our findings show that WM performance predicts later performance in problem solving accuracy, mathematical calculation, and knowledge of problem solving components. What are the implications of our findings to education of children? We believe the results have three implications.

1. Our classification criteria have predictive validity. Children identified at risk for SMD in Wave 1 were deficient in problem solving in Wave 3. Children identified at risk for SMD in Wave 1 did not catch up to children not at risk in Wave 3 in problem solving, math, and WM. Further, as shown in Figure 1, several other areas were found deficient in children identified at risk for serious mathematical problem solving difficulties (e.g., reading, random generation). Thus, our classification based on digit naming speed and the Arithmetic subtest of the WISC-III (which includes word problems) was a valid discriminator in predicting subsequent growth in Year 3.

Of course, one may criticize our classification criteria both in terms of the tasks we used, especially the Arithmetic subset of the WISC-III, and the cutoff criteria as well. Let us consider three arguments related to the Arithmetic subtest. One argument is that risk status should be based on calculation skill and not problem solving ability. However, we argue that we were able to identify a substantial number of children who were in the average range on reading and calculation measures but had clear difficulties listening to a problem with a verbal text and coming up with a correct solution. We are very much aware of the work by others (e.g., Geary, 2003), indicating that math disability should focus on calculation only. However, selection criterion for risk has varied across studies from the 25th percentile to the 45th percentile (see Swanson & Jerman, 2006, for a review). We think one of the reasons for this variation in cutoff scores is that standardized calculation scores have an extremely restrictive range of items for the younger grades and/or items do not match demands of the classroom. That is, popular standardized measures of calculation place children higher than actual classroom performance (e.g., see Fuchs et al., 2004, p. 496, for discussion of this issue). However, when problem solving difficulties were considered, we were able to sample enough children below a conservative cutoff score of the 25th percentile.

Another argument is that the Arithmetic subtest from the WISC-III was not intended as a measure of math. Although Sattler (2001) and others suggested that the Arithmetic subtest from the WISC-III was not intended to be a math measure, it is clearly correlated with math achievement, as well as vocabulary and other related skills. Regardless of the intent of the measure, the arithmetic subtest requires children to answer simple to complex problems involving arithmetic concepts and numerical reasoning. The first couple of problems require the direct counting of discrete objects. Problems 3, 4, and 5 require subtraction using objects and stimuli. The remaining problems require addition, subtraction, multiplication, and division.

Another argument is that the Arithmetic subtest itself is a WM measure. No doubt this task taps WM as well as prior learning, but it also correlates more highly with information and similarities than the other subtests (e.g., Digit Span). In fact, it has a *g* loading the same as Vocabulary, Information, and Similarities (see Keith et al., 2006, p. 122), whereas Digit Span is substantially lower.

Although we recognize that the mental computation required for this task does place constraints on WM capacity, the goal in our study was to find out which components of WM are the most constrained for children who have difficulties related to mental calculation.

In summary, our finding is important because children who were at risk for problem solving were generally in the average range on reading and math calculation measures but sustained difficulties on a number of measures across all testing waves.

2. A major cognitive component that underlies risk status in elementary school children with average intelligence is the executive component of WM. In contrast to the work on reading, it does not appear to be the case in this study that deficits in WM were merely a manifestation of deficits in the phonological system (also see Swanson & Ashbaker, 2000, for a similar finding). We found in our regression modeling that WM predicted math problem solving even when the influence of STM was partialled out.

The above finding is consistent with other studies showing that WM is an important predictor of various cognitive operations even when the influence of STM is partialled out in the analysis (e.g., Engle et al., 1999). Although we assumed that the residual variance related to WM was related to some aspect of the central executive system, most notably controlled attention, an important point raised by one anonymous reviewer of this article is that we have no direct measure indicating that the residual variance related to WM is controlled attention. Further, the reviewer also indicated that our findings are merely an artifact of *g*. For example, children at risk for SMD had lower Raven scores than those not at risk. However, it is important to note that fluid intelligence was partialled out in the analysis in Model 5. Even under these conditions, WM still contributed significant variance to word problem solving. However, the reviewer is correct that one cannot assume that the residual variance related to WM is controlled attention. Let us consider this point in more detail.

Our results extend Engle et al.'s (1999) findings to children that when controlling for the correlations between WM and STM, the residual variance for the WM factor predicts problem solving. The question emerges, however, as to whether the residual variance attributed to WM and problem solving reflects controlled attention (e.g., Engle et al., 1999), a domain general attentional resource involved in the activation of information from LTM (e.g., Cantor & Engle, 1993), a general monitoring system that coordinates the flow of information but draws from specialized storage systems (e.g., Baddeley & Logie, 1999), or a limited-capacity resource that supports both processing and storage in a domain-specific system (e.g., Just & Carpenter, 1992).

To answer this question, let us first consider Model 3 in Table 9. We assumed that some of the activities related to executive processing component of the WM measure (i.e., controlled attention) were related to the latent measures of fluency, random generation, and speed of processing. However, we found that entry of these measures in the regression models did not eliminate the significant contribution of WM to problem solving accuracy or calculation. What these findings suggest to us is that attentional processes dissimilar from those captured by measures of fluency, speed, and random generation mediate the residual variance related to WM in predicting problem solving. Further, because our measures were not pure measures of inhibition, we may not have adequately tested the inhibition model. Interestingly, in Model 5

(see Table 9), we found that both the executive and visual-spatial component of WM significantly predicted math problem solving when measures of literacy (reading and phonological knowledge) were entered into the regression model. Thus, weak support was found for the phonological model, because the entry of those variables into the regression analysis failed to partial out the influence of WM in predictions of problem solving. Thus, verbal forms of processing efficiency (naming speed) and content (phonological knowledge) did not adequately account for the influence of WM. On the basis of these results, we argue that if WM is made up of controlled attention and storage, then when the influence of storage is partialled out in the analysis, what is left in terms of residual variance is some form of controlled attention. However, given that the random generation, fluency tasks, and measures of LTM did not eliminate the contribution of this residual variance to word problem solving accuracy, we tentatively concluded that some yet-to-be-specified aspects of controlled attentional processing play an important predictive role in elementary school children's problem solving.

3. Limitations in WM capacity can be compensated for by improved fluency and proficiency on academic tasks (i.e., knowledge of problem solving components, reading comprehension, and math computation). Although the influence of individual differences in WM on problem solving performance is robust, this does not mean that its influence cannot be compensated for. Increased performance on measures related to math calculation and knowledge of algorithms reduced the influence of individual differences in WM on problem solving. What remains to be examined is the influence of instruction and age-related development on these processes. From a practical standpoint, the finding that WM tests do mediate problem solving outcomes should be considered when we look at high stakes examinations. Although our research suggests that literacy (reading) is important in terms of augmenting (predicting) word problem solving ability (see Model 4, Table 9), this is not the only variable that needs to be considered when compensating for demands on WM. The demands on reading are not greater than the demands on WM. In fact, the actual percentage of variance contributed to word problem solving ability is higher for the WM measures than it is for the literacy measures. The results do suggest that mathematical calculation skills are important in the study; so clearly there must be a threshold that would be extremely important. It appears that the children in this study had mastered or at least performed above the threshold and, therefore, were able to rely on other resources.

### Conclusion

In summary, growth in WM predicts growth on problem solving measures. We believe these results extend those studies on individual differences that suggest that a WM system plays a critical role in integrating information during problem solving. These models explicitly posit a dual role of WM: (a) It holds recently processed information to make connections to the latest input, and (b) it maintains information for the construction of an overall solution to problems. In terms of individual differences, children who have a large WM capacity for language can carry out the execution of various fundamental problem solving processes (such as problem representation, problem execution, etc.) with less demands on a limited resource pool than children with a smaller WM

capacity. As a result, children with a larger WM capacity would have more resources available for storage while representing the problem. On the other hand, children with a smaller WM capacity might have fewer resources available for the maintenance of information during problem solving. Further, this relationship holds (at least for children) even when the influence of phonological loop (naming speed and STM) is partialled from the analysis. Yet, WM is not the exclusive contributor to variance in problem solving ability. This study also supports previous research about the importance of reading skill in solution accuracy (see Model 4). Moreover, our findings are consistent with models of high order processing, which suggest that WM resources activate relevant knowledge from LTM but also suggest that a subsystem that controls and regulates the cognitive system plays a major role. What is unclear from previous studies is whether growth in the WM system is related to growth in problem solving. This study has provided clear evidence suggesting that growth in WM is related to growth in problem solving. Thus, we think one of the core problems children face in solving mathematical word problems relates to growth in operations ascribed to WM.

# Revising the Redundancy Principle in Multimedia Learning

Richard E. Mayer and Cheryl I. Johnson  
University of California, Santa Barbara

College students viewed a short multimedia PowerPoint presentation consisting of 16 narrated slides explaining lightning formation (Experiment 1) or 8 narrated slides explaining how a car's braking system works (Experiment 2). Each slide appeared for approximately 8–10 s and contained a diagram along with 1–2 sentences of narration spoken in a female voice. For some students (the redundant group), each slide also contained 2–3 printed words that were identical to the words in the narration, conveyed the main event described in the narration, and were placed next to the corresponding portion of the diagram. For other students (the nonredundant group), no on-screen text was presented. Results showed that the group whose presentation included short redundant phrases within the diagram outperformed the nonredundant group on a subsequent test of retention ( $d = 0.47$  and  $0.70$ , respectively) but not on transfer. Results are explained by R. E. Mayer's (2001, 2005a) cognitive theory of multimedia learning, in which the redundant text served to guide the learner's attention without priming extraneous processing.

**Keywords:** educational technology, multimedia learning, redundancy effect, PowerPoint presentation

Suppose you want to explain how lightning storms develop or how a car's braking system works to students who lack relevant prior knowledge, so you design a concise, narrated animation using the following research-based principles of effective instructional design (Fletcher & Tobias, 2005; Mayer, 2001, 2005b, 2005c, 2005d):

1. The *multimedia principle*—you use both words (as spoken text) and pictures (as animation or a series of still frames).
2. The *coherence principle*—you minimize any extraneous words or pictures.
3. The *modality principle*—you present the words as narration rather than as on-screen text.
4. The *temporal contiguity principle*—you present the narration at the same time the corresponding event is depicted in the graphics.

On subsequent retention tests (e.g., in which you ask the learner to write an explanation) or transfer tests (e.g., in which you ask the learner to write why the system might not work or how to improve it), learners perform better than if the principles were not implemented (e.g., no pictures were presented, extraneous words were included in the narration, or the narration was presented before or after the graphics).

What can you do to improve upon such seemingly effective lessons? You might be tempted to incorporate on-screen text, in which a caption appears at the bottom of the screen that contains the same words that are being spoken in the narration. As soon as the narrator begins a sentence, it appears on the bottom of the

screen, and it stays on the screen until the narrator finishes the sentence.

Does adding redundant on-screen text help students learn? Previous research has shown students learn better from multimedia lessons containing graphics and narration than from graphics, narration, and redundant on-screen text (Kalyuga, Chandler, & Sweller, 1999, 2000, 2004; Leahy, Chandler, & Sweller, 2003; Mayer, Heiser, & Lonn, 2001; Moreno & Mayer, 2002a, 2002b; Mousavi, Low, & Sweller, 1995). This finding is known as the *redundancy effect* (Mayer, 2001, 2005c). For example, in a study by Moreno and Mayer (2002b), participants viewed an animation about lightning formation. The first condition had narration accompany the animation, whereas a second condition received redundant on-screen text in addition to the animation and narration. The group that received the redundant on-screen text performed worse on subsequent retention and transfer questions than did the group that received animation and narration; thus, a redundancy effect was found.

In most of the studies investigating the redundancy effect, including the one just discussed, the narration and the on-screen text were identical (Mayer, 2005c; Sweller, 1999, 2005), thus violating the coherence principle which, as mentioned above, states that unnecessary words or graphics should be eliminated (Mayer, 2001, 2005c). In addition, in many of the studies, including the one just discussed, the text was presented at the bottom of the screen, thus violating the *spatial contiguity principle*, which states that corresponding words and pictures in a multimedia presentation should be presented near each other on the screen (Ayres & Sweller, 2005; Mayer, 2001, 2005c).

Why does redundancy hinder learning? According to the cognitive theory of multimedia learning (Mayer, 2001, 2005a) shown in Figure 1, meaningful learning occurs when learners are able to pay attention to relevant portions of the words and graphics as they are registered in sensory memory (i.e., indicated by the "selecting words" and "selecting images" arrows), mentally organize them into coherent cognitive structures in working memory (i.e., indi-

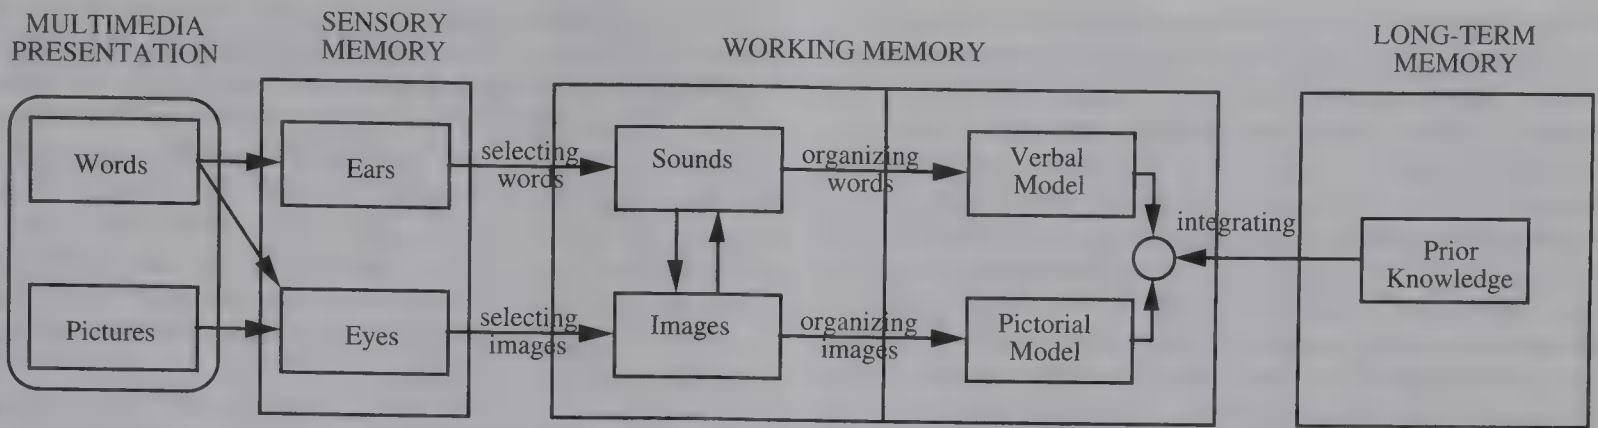

Figure 1. Cognitive theory of multimedia learning.

cated by the “organizing words” and “organizing images” arrows), and connect the verbal and pictorial representations with each other and with relevant knowledge retrieved from long-term memory (i.e., indicated by the “integrating” arrows). Although the integrating arrows are shown in working memory, the model assumes that the newly constructed knowledge is stored in long-term memory (using a process that can be called *encoding*).

Overall, the instructional message should be designed to reduce extraneous processing (i.e., processing that does not contribute to learning, such as visual scanning between the printed captions and the graphics), manage essential processing (i.e., processing aimed at selecting the relevant words and images so they can be represented in working memory), and foster generative processing (i.e., deeper processing in which the learner organizes and integrates the material). Adding redundant on-screen text detracts from the learning processes highlighted in Figure 1 because it creates extraneous processing—such as inducing the learner to visually scan between the caption at the bottom of the screen and the graphic and to try to mentally reconcile the incoming spoken and verbal stream. If the learner has to waste limited cognitive capacity on extraneous processing, the learner will be less able to engage in the cognitive processing needed for learning—essential and generative processing.

In spite of these empirical and theoretical setbacks for adding redundant on-screen text, in the current study we sought to determine whether there are conditions under which redundant on-screen text can foster rather than hinder learning. Consider a multimedia presentation on lightning formation consisting of 16 PowerPoint slides, each accompanied by approximately 10 s of narration, such as exemplified in the left panel of Figure 2 (i.e., the nonredundant presentation). To help learners direct their auditory attention to the key event being described in the narration, we can print a two- or three-word description of the event on the screen (using words from the narration). To help learners direct their visual attention to the key portion of the diagram, we can place the words next to the event they describe in the diagram. The right panel of Figure 2 exemplifies how we implemented the redundant words in the diagram (i.e., the redundant presentation). The goal of this manipulation is to facilitate the first step in the cognitive theory of multimedia learning—*selecting relevant words and images* (Mayer, 2001, 2005a). Success in selecting relevant words and images is most important for subsequent tests of retention of the presented material. Thus, based on the cognitive theory of multimedia learning, we predicted that the redundant group would outperform the nonredundant group on a retention test.

Figure 2. Example slide from the nonredundant (left panel) and redundant (right panel) versions of the lightning lesson.

This implementation of redundancy as short, on-screen labels avoids two major problems with previously studied redundancy presentations in which the entire text of the narration is printed at the bottom of the screen. First, by using only two or three keywords, the learner does not have to engage in reading the entire sentence; second, by placing the words next to the corresponding elements in the diagram, the learner does not need to scan from the bottom of the screen to various points in the diagram. Thus, we have attempted to create redundancy in a way that minimizes extraneous cognitive processing (namely, not requiring the learner to read an entire sentence or visually scan the diagram) while facilitating essential cognitive processing (namely, guiding the learner's selection of relevant words and images). Based on this interpretation of the cognitive theory of multimedia learning, we predict that adding on-screen labels to narrated graphics will result in improved performance on tests of retention (which are intended to be sensitive to instruction that guides the learner's attention) and will not hinder performance on tests of transfer (which are intended to measure deeper processing during learning). It is possible that the treatment could improve performance on transfer by freeing up cognitive capacity to engage in deeper processing, although the main manipulation in this study is intended to pinpoint the most important words in the narration.

### Experiment 1 (Lightning)

The purpose of Experiment 1 was to determine the cognitive consequences of adding short, redundant on-screen text to a multimedia lesson.

#### *Participants and Design*

Ninety undergraduates from the University of California, Santa Barbara, psychology student subject pool participated in this study for course credit. The mean age was 18.29 years ( $SD = .75$ ), and there were 58 women and 32 men. Forty-five participants served in the nonredundant group, and 45 participants served in the redundant group.

#### *Method*

**Materials and apparatus.** The paper-based materials consisted of a participant questionnaire, a retention test question, and four transfer test questions, each typed on an 8.5- × 11-in. sheet of paper. The participant questionnaire solicited information concerning the participant's age, sex, and prior knowledge. The retention test question was "Please write down an explanation of how lightning works." The retention test was intended to measure the student's memory for the presented material—corresponding to remembering factual and conceptual knowledge in Bloom's taxonomy (Anderson et al., 2001). The transfer test questions were as follows: (a) "What could you do to decrease the intensity of lightning?" (b) "Suppose you see clouds in the sky but no lightning. Why not?" (c) "What does air temperature have to do with lightning?" and (d) "What causes lightning?" The transfer test was intended to measure the student's understanding of the presented material—corresponding to understanding and applying conceptual knowledge in Bloom's taxonomy (Anderson et al., 2001).

The computer-based materials consisted of nonredundant and redundant versions of a PowerPoint lesson on lightning formation. The presentation included diagrams and simultaneous narration shown via PowerPoint and consisted of 16 individual slides, lasting approximately 2.5 min. The slides advanced automatically after the narration was complete, averaging approximately 9.5 s per slide. The slides for the redundant group included two or three action-oriented keywords from the narration and were presented within the diagram next to the elements they described. The words expressed the main action depicted in the slide. For example, for the slide containing the narration, "Cool moist air moves over a warmer surface and becomes heated," the keywords "air becomes heated" were printed in the diagram next to the heated air mass. The slides for the nonredundant group contained no printed words. Examples of redundant and nonredundant slides are shown in Figure 2.

The apparatus consisted of five Macintosh iBook computers with Panasonic headphones. A stopwatch was used to time the retention and transfer tests.

**Procedure.** Students were tested in groups of 1 to 5 per session, with each student seated in an individual cubicle containing a Macintosh iBook computer with Panasonic headphones. Students were told they would view a lesson on lightning formation and then they would answer some questions based on the material. Each student completed the participant questionnaire, then watched a short PowerPoint presentation about lightning formation on the computer, and finally answered a series of timed, open-ended questions about the material consisting of one retention question and four transfer questions. Half of the participants were randomly assigned to the nonredundant group (which received graphics and narration), and half were randomly assigned to the redundant group (which received graphics, narration, and on-screen text). Following the presentation, all students wrote their answers for the retention test question (with a 5-min time limit) and each of the transfer test questions (with a 3-min time limit per question). Upon completion of the tests, students were thanked and debriefed. The materials and procedure were adapted from previous research using a narrated animation on lightning formation (Mayer et al., 2001; Moreno & Mayer, 2002b).

#### *Results and Discussion*

The dependent variables were the scores on the retention and transfer tests; the independent variable was whether or not the presentation included redundant text. In order to score the retention test, we broke the lightning script into 16 idea units, each expressing a main event such as "cool air moves over warmer surface and becomes heated." Each student's retention test was scored by assigning 1 point for each idea unit that the student wrote down, regardless of wording or spelling (out of a total possible of 16 points), such as "cold air gets hotter." For the transfer tests, a list of acceptable answers was created for each question. For example, for the question about decreasing the intensity of lightning, correct answers included removing positive ions from the ground and placing positive ions near the cloud. One point was awarded for each correct answer, and the points for each question were added up to compute the total transfer score (out of a total possible of 12 points), which was used in the analyses.

Table 1 presents the means and standard deviations of the two groups on the retention and transfer tests. Independent samples *t* tests revealed that the redundant group ( $M = 8.02$ ,  $SD = 2.83$ ) scored significantly better than the nonredundant group ( $M = 6.69$ ,  $SD = 2.87$ ) on the retention test,  $t(88) = 2.22$ ,  $p < .05$ ,  $d = 0.47$ , whereas the redundant group ( $M = 3.60$ ,  $SD = 2.00$ ) and the nonredundant group ( $M = 3.67$ ,  $SD = 2.04$ ) did not differ significantly on the transfer test,  $t(88) = 0.16$ ,  $p = .88$ ,  $d = 0.04$ .

Results can be explained in terms of Mayer's (2001, 2005a) cognitive theory of multimedia learning. Essential processing was fostered by the redundant treatment because the on-screen text helped guide the learners' attention to the relevant words—which was reflected in retention test performance. However, the redundant on-screen text was not intended to encourage generative processing (i.e., deeper cognitive processing), such as organizing the material into a coherent representation and integrating it with existing knowledge—which would be reflected in transfer test performance. Extraneous processing was kept low in the redundant condition by minimizing the amount of on-screen text (rather than reproducing all of the text) and placing it next to the corresponding portion of the diagram (rather than at the bottom).

### Experiment 2 (Brakes)

The purpose of Experiment 2 was to determine whether the pattern of results obtained in Experiment 1 could be replicated with different instructional materials.

#### Participants and Design

Sixty-two undergraduate students from the University of California, Santa Barbara, psychology student subject pool participated in this study for course credit. The mean age of participants was 18.6 years ( $SD = 1.2$ ), and there were 27 women and 35 men. Thirty-one participants served in the nonredundant group, and 31 participants served in the redundant group.

#### Method

**Materials and apparatus.** The paper-based materials consisted of a participant questionnaire, a retention test question, and five transfer test questions, each typed on an 8.5- × 11-in. sheet of paper. The participant questionnaire solicited information concerning the participant's age, sex, and prior knowledge. The retention test question was "Please write down an explanation for how a car's braking system works." The transfer test questions were as

follows: (a) "Why do brakes get hot?" (b) "What could be done to make brakes more reliable, that is, to make sure they do not fail?" (c) "What could be done to make brakes more effective, that is, to reduce the distance needed to bring the car to a stop?" (d) "Suppose you press on the brake pedal in your car but the brakes don't work. What could have gone wrong?" and (e) "What happens when you pump the brakes (i.e., press the pedal and release the pedal repeatedly and rapidly)?"

The computer-based materials consisted of nonredundant and redundant versions of a PowerPoint lesson on how a car's braking system works. The presentation included diagrams and simultaneous narration shown via PowerPoint and consisted of eight individual slides, lasting approximately 80 s. The slides advanced automatically after the narration was complete, averaging approximately 10 s per slide. The slides for the redundant group included two or three action-oriented keywords from the narration and were presented within the diagram next to the elements they described. The words expressed the main action in the slide. For example, for the slide containing the narration, "a piston moves forward inside the master cylinder," the keywords "piston moves forward" were printed in the diagram next to the piston in the master cylinder. The slides for the nonredundant group contained no printed words. An example of a redundant slide is presented in Figure 3.

The apparatus consisted of five Macintosh iBook computers with Panasonic headphones. A stopwatch was used to time the retention and transfer tests.

**Procedure.** Students were tested in groups of 1 to 5 per session, with each student seated in an individual cubicle containing a Macintosh iBook computer with Panasonic headphones. Students were told they would view a lesson on how car brakes work, and then would answer some questions based on the material in the lesson. Each student completed the participant questionnaire, then watched a short PowerPoint presentation about car brakes on the computer, and finally answered a series of timed, open-ended questions about the material consisting of one retention question and five transfer questions. Half of the participants were randomly assigned to the nonredundant group (which received graphics and narration), and half were randomly assigned to the redundant group (which received graphics, narration, and on-screen text). Following the presentation, all students wrote their answers for the retention test question (with a 4-min time limit) and each of the transfer test questions (with a 2.5-min time limit per question). Upon completion of the tests, students were thanked and debriefed. The materials and procedure were adapted from previous research using a narrated animation on how brakes work (Mayer & Anderson, 1991; Mayer & Moreno, 1998).

#### Results and Discussion

The dependent variables were the scores on the retention and transfer tests; the independent variable was whether or not the presentation included redundant text. The retention tests were scored by breaking the lesson into eight idea units, each conveying one action, such as "the piston moves forward in the master cylinder." Students received 1 point for each idea unit they wrote down on their retention test (out of a total possible of 8 points), regardless of spelling or wording. For the transfer tests, we developed a list of acceptable answers for each question. For example, for the question about what could be wrong, possible answers

Table 1  
Mean Retention and Transfer Scores for Two  
Groups—Experiment 1 (Lightning Lesson)

Score type and group	<i>M</i>	<i>SD</i>	<i>p</i>	<i>d</i>
Retention				
Nonredundant	6.7	2.9	.03	0.47
Redundant	8.0	2.8		
Transfer				
Nonredundant	3.6	2.0	.88	0.04
Redundant	3.7	2.0		

Figure 3. Slide from the redundant version of the brake lesson; the nonredundant version did not contain the on-screen text.

included that the piston was stuck or there was a leak in the brake tube. One point was awarded for each correct answer, and the points for each question were added up to compute the total transfer score (out of 14 possible points), which was used in the analyses.

Table 2 summarizes the means and standard deviations for the two groups on the retention and transfer tests. Independent samples *t* tests revealed that the redundant group ( $M = 5.13$ ,  $SD = 1.98$ ) scored significantly better than the nonredundant group ( $M = 3.61$ ,  $SD = 2.35$ ) on the retention test,  $t(60) = 2.75$ ,  $p = .008$ ,  $d = 0.70$ , whereas the redundant group ( $M = 3.90$ ,  $SD = 1.76$ ) and the nonredundant group ( $M = 4.16$ ,  $SD = 2.16$ ) did not differ significantly on the transfer test,  $t(60) = 0.52$ ,  $p = .608$ ,  $d = 0.15$ .

The pattern of results in Experiment 2 replicates that in Experiment 1 and supports the theoretical explanation that short, redundant on-screen text can guide the learner's attention toward relevant words (i.e., essential processing) without increasing extraneous processing or fostering generative processing.

## Conclusion

### Main Empirical Findings

In two separate experiments, adding short, redundant text to narrated graphics resulted in improvements on retention of the

verbal material but not on transfer. The effect size—favoring the redundant group—was in the medium range, indicating that the redundancy effect was practically important as well as statistically significant.

### Theoretical Implications

The pattern of results is consistent with the predictions of the cognitive theory of multimedia learning, in which short on-screen labels are intended to guide the cognitive process of selecting relevant words and images while not creating extraneous processing. In previous studies, adding redundant on-screen text to narrated graphics (i.e., complete reproductions of the narration as captions at the bottom of the screen) resulted in decreases in both retention and transfer test performance (Mayer, 2001, 2005c).

There were three main differences in the way redundancy was implemented in the present study in comparison with previous studies that yielded a redundancy effect. First, the on-screen text was short rather than long: Short text, consisting of two or three words, was intended to guide essential processing while not creating extraneous processing, whereas long on-screen text does not guide essential processing while creating the need for extraneous processing.

Second, the on-screen text was placed near rather than far from the corresponding portion of the graphic: Contiguous presentation of corresponding words and graphics is intended to minimize extraneous processing while guiding the learner's attention toward the relevant portion of the graphic, whereas separated presentation induces extraneous processing while not guiding the learner's attention. When sentences from the narration are printed in their entirety as text at the bottom of the screen, learners may engage in extraneous cognitive processing that results in poorer performance on subsequent tests (Mayer, 2001, 2005c). In contrast, when a few keywords are printed next to the corresponding portion of the diagram, learners may be better able to engage in essential cognitive processing (such as selecting relevant words and images) that results in improved performance on subsequent tests.

Table 2  
Mean Retention and Transfer Scores for Two Groups—Experiment 2 (Brakes Lesson)

Score type and group	<i>M</i>	<i>SD</i>	<i>p</i>	<i>d</i>
Retention				
Nonredundant	3.6	2.3	.008	0.70
Redundant	5.1	2.0		
Transfer				
Nonredundant	4.2	2.2	.61	0.15
Redundant	3.9	1.8		

Table 3  
When Redundancy Supports or Hinders Learning

Action	Condition
Redundancy supports learning	When it minimizes extraneous processing—by placing text near rather than far from corresponding graphics When it fosters essential processing—by highlighting key portions of the text rather than presenting all text (or when text is complex)
Redundancy hinders learning	When it creates extraneous processing—by placing text far from rather than near corresponding graphics When it detracts from essential processing—by highlighting the entire text rather than highlighting key portions of the text

Third, the present study presented graphics as a series of static illustrations rather than as an animation as in previous experiments. The motion in an animation may help direct the learner's attention to the relevant portion of the graphic, but there are no motion cues in a static illustration. Therefore, redundant on-screen phrases may be particularly helpful for directing the learner's attention with static illustrations.

### Practical Implications

Concerning educational implications, this study helps to establish some boundary conditions for determining when redundancy can be helpful or harmful in multimedia learning. The most straightforward contribution of this work is to add an important caveat to the redundancy principle "People learn more deeply from graphics and narration than from graphics, narration, and on-screen text" (Mayer, 2005c, p. 193).<sup>1</sup> In revising this statement of the redundancy principle, we can add the following limitation: "except when the on-screen text is short, highlights the key action described in the narration, and is placed next to the portion of the graphic that it describes." In short, this work pinpoints an important boundary condition for applying the redundancy principle—it applies most strongly when the on-screen text reproduces the complete narration and appears at the bottom of the screen, and it does not necessarily apply when the on-screen text consists of a few core words placed next to the relevant portion of the graphic. Table 3 summarizes the conditions under which redundancy can hinder or help learning. We also suspect that other boundary conditions include when the spoken text is complex, contains unfamiliar words, or is not in the learner's native language; when the pace of the presentation is slow or under the learner's control; or when no graphics are presented (Mayer, 2001, 2005c).

A broader contribution of this work is to highlight the admonition that design principles for multimedia messages, such as the 10 principles proposed by Mayer (2001, 2005b, 2005c, 2000d), are not rigid laws that must be followed in all circumstances. Rather, decisions about appropriate instructional design should be based on an understanding of how people learn from words and pictures, such as the cognitive theory of multimedia learning (Mayer, 2001, 2005a) or cognitive load theory (Sweller, 1999, 2005). Thus, the challenge for instructional designers is to apply design principles in ways that reduce extraneous processing (such as scanning between captions and the graphic), manage intrinsic processing (such as attending to relevant portions of the narration and graphic), and foster generative processing (such as mentally organizing and integrating the material). The revision to the redundancy principle is necessary because the use of short labels helps

manage essential processing (by guiding the learner's attention to the keywords in the narration and the key action in the graphic) while not adding to extraneous processing (by presenting only a few words and placing them next to the portion of graphic they describe). In summary, rather than blindly following design rules, instructional designers should always consider how applying a rule will affect the learner's cognitive processing during learning, particularly the degree to which applying the principle is likely to lead to reducing extraneous processing, managing intrinsic processing, and fostering generative processing.

### Limitations and Future Directions

These studies were conducted as short laboratory experiments, but future work is needed to determine whether the findings generalize to more realistic educational settings. Future work also is needed to determine whether the results would be obtained if the words in the narration were presented as on-screen captions rather than narration. Finally, although there were no differences between the groups on the transfer test, it is possible that more sensitive measures might be able to detect a difference in future work. However, the transfer scores were not near either ceiling or floor, and the same transfer test has yielded significant differences between treatment groups in other experiments (Mayer, 2001).

<sup>1</sup> Sweller (1999, 2005) uses a broader definition of the redundancy principle in which learning is hindered when "the same material is presented in multiple forms" (Sweller, 2005, p. 159). This definition includes our definition of redundancy but also includes additional situations that we did not investigate.

## Low Publication Prices for APA Members and Affiliates

**Keeping you up-to-date.** All APA Fellows, Members, Associates, and Student Affiliates receive—as part of their annual dues—subscriptions to the *American Psychologist* and *APA Monitor*. High School Teacher and International Affiliates receive subscriptions to the *APA Monitor*, and they may subscribe to the *American Psychologist* at a significantly reduced rate. In addition, all Members and Student Affiliates are eligible for savings of up to 60% (plus a journal credit) on all other APA journals, as well as significant discounts on subscriptions from cooperating societies and publishers (e.g., the American Association for Counseling and Development, Academic Press, and Human Sciences Press).

**Essential resources.** APA members and affiliates receive special rates for purchases of APA books, including the *Publication Manual of the American Psychological Association*, and on dozens of new topical books each year.

**Other benefits of membership.** Membership in APA also provides eligibility for competitive insurance plans, continuing education programs, reduced APA convention fees, and specialty divisions.

**More information.** Write to American Psychological Association, Membership Services, 750 First Street, NE, Washington, DC 20002-4242.

# Does Extrinsic Goal Framing Enhance Extrinsic Goal-Oriented Individuals' Learning and Performance? An Experimental Test of the Match Perspective Versus Self-Determination Theory

Maarten Vansteenkiste  
Ghent University

Tinneke Timmermans and Willy Lens  
University of Leuven

Bart Soenens  
Ghent University

Anja Van den Broeck  
University of Leuven

Previous work within self-determination theory has shown that experimentally framing a learning activity in terms of extrinsic rather than intrinsic goals results in poorer conceptual learning and performance, presumably because extrinsic goal framing detracts attention from the learning activity and is less directly satisfying of basic psychological needs. According to the match perspective, experimental extrinsic, compared to intrinsic, goal framing should enhance learning and performance for learners who personally hold a stronger extrinsic than intrinsic goal orientation, as these learners' personally held goals match with the situationally induced goals. An experimental field study among 5th–6th grade children shows that extrinsic goal framing resulted in poorer autonomous motivation, conceptual (but not rote) learning, and persistence compared to intrinsic goal framing, irrespective of participants' personal intrinsic versus extrinsic goal orientations and their spontaneous perception of the learning activity as serving an intrinsic or an extrinsic goal. The authors conclude that teachers can best promote intrinsic goals, even when facing students who personally hold a stronger extrinsic than intrinsic goal orientation.

**Keywords:** intrinsic versus extrinsic goals, match perspective, self-determination theory

Values represent categories of desirable life goals, varying in importance, that serve as a guiding principle in people's lives (De Witte, 2004; Rohan, 2000; Rokeach, 1973; Schwartz, 1992, 1999). Various researchers have developed multidimensional models of the interpersonal variation in the type of values (Schwartz, 1994) or life goals (Grouzet et al., 2006; Nuttin & Lens, 1985) that people hold.<sup>1</sup> In addition, researchers have been interested in studying the implications of people's life goals for their well-being and achievement. In doing so, they have proposed at least two different and conflicting perspectives. Some researchers, drawing on SDT (Deci & Ryan, 1985, 2000; Ryan & Deci, 2000b), hold that some goals are better than others for people's thriving and optimal functioning (Kasser, 2002; Vansteenkiste, Lens, & Deci, 2006). Other researchers claim that there does not exist a category of more adaptive values or life goals (e.g., Bianco, Higgins, & Klem, 2003; Sagiv & Schwartz, 2000; Walsh & Holland, 1992). They have argued that the relation between people's life goals,

achievement, and adjustment depends on the match or fit between people's personal goal orientations and the goals that are emphasized and encouraged in the direct environment (Pervin, 1968; Schneider, 1987). This viewpoint is commonly referred to as the *match perspective*.

A few previous studies have directly examined the conflicting hypotheses that can be derived from SDT and the match perspective (Kasser & Ahuvia, 2002; Sagiv & Schwartz, 2000; Vansteenkiste, Duriez, Simons, & Soenens, 2006), but they were all correlational in nature and focused on well-being outcomes only. The current contribution goes beyond past work by providing evidence from an experimental field study that focused on learning and performance outcomes. Before detailing the aims of the present research, we introduce both theoretical perspectives.

<sup>1</sup> It should be noted that there exists a slight conceptual difference between values and life goals, as the latter are more concrete and lower order units, whereas the former are rather abstract and higher order units (Grouzet et al., 2006; Schwartz, 1994). The conceptual difference between the constructs is, however, of less importance to the present study, which focuses on the match between personally held life goals or values and the type of life goals or values that are promoted by the social environment. We adopted the term *goals* throughout the article because this is the term that is most commonly used within research on self-determination theory (SDT).

## Self-Determination Theory

### *Intrinsic and Extrinsic Motivation and Intrinsic and Extrinsic Goal Contents*

The classic motivation constructs that have received the most empirical and theoretical attention within SDT and other motivational frameworks are intrinsic and extrinsic motivation (Deci & Ryan, 2000; Vansteenkiste, Lens, & Deci, 2006). Whereas *intrinsic motivation* refers to engaging in an activity for its own sake, simply because it is enjoyable and gratifying by itself, *extrinsic motivation* refers to engaging in an activity to obtain an outcome separable from the activity itself (Ryan & Deci, 2000a). In earlier theorizing in the 1970s (e.g., Lepper & Greene, 1978), intrinsic and extrinsic motivation were considered as antipodes, with intrinsic motivation representing the most autonomous or self-determined type of motivation and extrinsic motivation representing a nonautonomous or controlled type of motivation. However, subsequent empirical work in the 1980s (e.g., Ryan, Mims, & Koestner, 1983) made clear that not all extrinsically motivated behavior is nonautonomous, given that individuals are able to volitionally endorse (i.e., internalize) the reasons for engaging in the activity at hand. This insight resulted in a conceptual shift within SDT away from the intrinsic–extrinsic motivation dichotomy toward the distinction between autonomous motivation, which involves both intrinsic and well-internalized motivation, and controlled motivation, which involves poorly internalized or non-internalized motivation. Thus, autonomous and controlled motivation represent two qualitatively different types of reasons for regulating one's behavior and are often studied under the label of the “why” of behavior (Deci & Ryan, 2000; Vansteenkiste, Lens, & Deci, 2006; Vansteenkiste, Ryan, & Deci, in press).

Parallel to the growing attention to the concepts of autonomous and controlled motivation, SDT researchers have also been paying attention to people's goal contents or goal orientations (Kasser & Ryan, 1993). In this respect, Kasser and Ryan (1993, 1996) differentiated extrinsic goals, such as wealth, physical appeal, and social recognition, from intrinsic goals, such as affiliation, personal growth, and community contribution, on the basis of humanistic (Maslow, 1954) and existential (Fromm, 1976) theorizing. Intrinsic goals reflect people's natural growth tendencies and are characterized by an inwardly oriented frame. In contrast, when people pursue extrinsic goals, they tend to adopt an outward orientation (Williams, Cox, Hedberg, & Deci, 2000)—that is, they are focused on impressing others by garnering external signs of self-worth. These different goal contents are often studied under the label of the “what” of behavior within SDT (Deci & Ryan, 2000).

According to SDT, intrinsic and extrinsic goals, which represent qualitatively different types of goals, can be motivated by autonomous or controlled reasons, which represent qualitatively different types of motivations and thus distinct sets of constructs. For instance, a person can be altruistic (i.e., an intrinsic goal) because he or she enjoys pursuing this goal (autonomous motivation) or because he or she would feel bad if he or she did not help people in need (controlled motivation). Similarly, a person can be focused on becoming famous (i.e., an extrinsic goal) because his or her parents pressure him or her to be a well-known person (controlled motivation) or because he or she personally values fame (autonomous motivation).

In the present research, we explicitly focused on the concepts of intrinsic and extrinsic goal orientations. More specifically, we examined whether framing a learning activity in terms of the attainment of intrinsic or extrinsic goals would yield a differential impact on the learning and persistence of intrinsic and extrinsic goal-oriented individuals. To clarify this overall aim, we first elaborate more on the concepts of intrinsic and extrinsic goal contents and their effects, as they have been studied from the SDT perspective.

### *The Effects of Intrinsic Versus Extrinsic Goal Contents*

SDT starts with the central assumption that all individuals are born with the basic psychological needs for autonomy, competence, and relatedness. The satisfaction of these psychological needs is regarded as necessary nutrients for individuals' optimal performance, well-being, and development, much as plants need water and sunshine to flower (Deci & Ryan, 2000; Ryan & Deci, 2000b). To understand the effects of goal contents on people's optimal functioning, one needs to answer the question of how goal pursuit is related to the satisfaction of the basic psychological needs. In this respect, intrinsic goals are said to facilitate psychological well-being, because they provide direct satisfaction of the basic and universal psychological needs for competence, autonomy, and relatedness (Deci & Ryan, 2000; Kasser, 2002). For instance, when people endorse the intrinsic goal of self-development, they are more likely to engage in challenging activities in a task-focused manner, which increases their chances of gaining a sense of competence. When people value the development of close relationships, they are more likely to empathically take the perspective of others, which might facilitate a sense of mutual connectedness and thrust (Kasser, 2002; Vansteenkiste, Neyrinck, et al., 2007; Vansteenkiste, Soenens, & Lens, 2007).

Although extrinsic goal pursuit might provide some satisfaction, this type of satisfaction is likely to be derivative and short lived, because extrinsic goal pursuits do not directly satisfy individuals' basic psychological needs (Deci & Ryan, 2000; Kasser, 2002; Kasser, Ryan, Couchman, & Sheldon, 2004). For instance, extrinsic goal-oriented individuals tend to approach others in an “objectifying” manner (Kasser, 2002)—that is, to treat them as objects that should be used in the most efficient way toward one's extrinsic goal attainment. Further, (learning) activities are approached in a restricted and rigid manner (Vansteenkiste, Simons, Lens, Soenens, & Matos, 2005); that is, extrinsic goal-oriented individuals only put effort into the activity as far as this will help them in achieving their extrinsic ambitions. Thus, they are less deeply involved in learning tasks because engagement in such tasks is only valued to the extent that they are instrumental for reaching extrinsic goals (Vansteenkiste, Simons, Lens, Soenens, et al., 2004). Such an objectifying and narrow-focused approach is, however, unlikely to create opportunities for satisfaction of the basic psychological needs for relatedness, competence, and autonomy. Consistent with these claims, Vansteenkiste, Neyrinck, et al. (2007) found in a sample of employees that an extrinsic, relative to an intrinsic, goal pursuit hindered basic need satisfaction.

Because of their differential linkage to the satisfaction of basic psychological needs, intrinsic versus extrinsic goals differentially predict psychological well-being (Ryan, Sheldon, Kasser, & Deci, 1996). In line with this reasoning, previous research has docu-

mented that when participants' life aspirations are more strongly centered around the pursuit of extrinsic rather than intrinsic goals, they display lower psychological well-being and social adjustment and are more vulnerable to ill-being and drug and alcohol abuse (see Kasser, 2002; Kasser et al., 2004, for an overview). Although most of this work has been conducted among late adolescent and adult samples, a few studies have suggested that early adolescents (Cohen & Cohen, 1996) and children (Kasser, 2005) also suffer emotionally from adopting an extrinsic or materialistic goal orientation.

It is interesting that SDT maintains that the pursuit of extrinsic, relative to intrinsic, goals should hinder the learning process and individuals' broader psychosocial adjustment, even when extrinsic goals are highly emphasized by the social environment—that is, in spite of a person–environment match in extrinsic goals. This is because extrinsic goals, by their very nature, are less likely to facilitate the satisfaction of basic human (organismic) needs, which functions as the “input” for all individuals' optimal functioning. Consistent with this, Kasser and Ahuvia (2002) and Vansteenkiste, Duriez, et al. (2006) found that extrinsic, relative to intrinsic, goal pursuit was associated with lower well-being and more internal distress among a group of business students (see also Srivastava, Locke, & Bartol, 2001), even though extrinsic goals tend to be heavily emphasized in business environments (Holland, 1985).

More recently, Vansteenkiste and colleagues (see Vansteenkiste, Lens, & Deci, 2006, for an overview) extended this work by examining the impact on participants' learning and performance of experimentally framing a learning activity in terms of an intrinsic versus extrinsic goal attainment. Thus, instead of treating intrinsic versus extrinsic goal contents as an individual-differences characteristic, they studied goal contents from a social contextual viewpoint—that is, by considering the extent to which goal contents are promoted by the social environment. On the basis of SDT, it was reasoned that intrinsic goals concern learning in the service of inherent psychological needs and growth tendencies and, hence, should promote learning. In contrast, extrinsic goals, with their focus on external indicators of worth, are more likely to distract people from the learning activity and, hence, should result in poorer learning. In a series of experimental field studies, it was found that framing a learning activity in terms of the attainment of an intrinsic goal enhanced conceptual learning, performance, and persistence compared to (a) an extrinsic goal-framing condition (Vansteenkiste, Simons, Lens, Sheldon, & Deci, 2004), (b) a double (i.e., intrinsic plus extrinsic) goal-framing condition (Vansteenkiste, Simons, Lens, Soenens, et al., 2004), and (c) a no-goal control condition (Vansteenkiste, Simons, Soenens, & Lens, 2004), whereas extrinsic goal framing undermined learning and performance both compared to the double goal-framing condition and the no-goal control condition. These findings were replicated among 11–12-year-old children (Vansteenkiste et al., 2005).

Although research has shown that experimental extrinsic, relative to intrinsic, goal framing undermines conceptual learning and performance, the question should be raised regarding whether these negative effects also apply to individuals who are, by themselves, more strongly oriented toward the pursuit of extrinsic than intrinsic goals. On the basis of the match perspective, it can be suggested that the negative effects of extrinsic goal framing are limited to learners who value intrinsic goals over extrinsic goals

and that the overall enhancement of learning and persistence in the intrinsic goal conditions of the studies reviewed earlier was carried primarily by those learners whose goal orientation was more intrinsic than extrinsic. To better understand the hypothesis derived from the match perspective, we describe this perspective in more detail below.

### The Match Perspective

The match perspective posits that the effect of the content of people's goal pursuits depends on the match or fit between the goal content and the type of goals that are emphasized in the interpersonal environment (Sagiv & Schwartz, 2000). The theme of match or fit between the person and the environment is represented in a broad array of fields in psychological research, as diverse as social (e.g., Sagiv & Schwartz, 2000), educational (e.g., Harackiewicz & Elliot, 1998), organizational (e.g., Edwards, 1991; Meglino, Ravlin, & Adkins, 1989; Ostroff, 1993; Ostroff, Shin, & Kinicki, 2005; Pervin, 1968), developmental (e.g., Eccles, Lord, & Midgley, 1991), and sport (e.g., Amiot, Vallerand, & Blanchard, 2006) psychology. However, most of this work, except for Sagiv and Schwartz (2000), concerned the examination of a person–environment match in goals other than the intrinsic–extrinsic goal dimension outlined within SDT. Hence, the present research extends previous work on the match perspective by examining whether the match perspective also holds with regard to the theoretical distinction between intrinsic and extrinsic goals, which has received increasing empirical attention in the educational and motivational literature (see Vansteenkiste, Lens, & Deci, 2006).

Sagiv and Schwartz (2000) claimed that the negative effect of extrinsic, relative to intrinsic, goal pursuits should be reversed when people find themselves in an extrinsic goal context that emphasizes extrinsic goals over intrinsic goals. They provided three related mechanisms to explain this matching effect. First, social environments that match individuals' goals afford better opportunities to translate one's goals into plans, to carry out one's plans, and, hence, to attain one's goals. Second, when people reject the goals and values that prevail in their environment, they may be ignored, ostracized, or sanctioned, while acceptance of the socially promoted goals is likely to elicit social support and reinforcement, which should promote well-being. Third, the internal conflict that people experience when their earlier acquired goals are in conflict with the goals supported by the social environment is also likely to forestall their well-being.

In line with the match perspective, Sagiv and Schwartz (2000), relying on Schwartz's (1992) value classification, showed in a sample of psychology and business students that the effect of valuing extrinsic goals over intrinsic goals on well-being interacted with participants' study environment. Business students who valued extrinsic goals over intrinsic goals reported higher psychological well-being, while psychology students reported more optimal functioning when they valued intrinsic goals over extrinsic goals.

The present study builds on the work of Sagiv and Schwartz (2000), because it examined whether the experimental induction of an intrinsic versus an extrinsic goal prior to engagement in a learning activity differentially affected learning and performance among children who valued intrinsic goals over extrinsic goals versus children who valued extrinsic goals over intrinsic goals.

Although the three mechanisms reviewed above are primarily relevant for the issue of well-being, the third mechanism (i.e., internal conflict) might also help us to understand the effects of match versus mismatch on learning and performance. That is, the third mechanism suggests that when learners are placed in a mismatch condition, they face an internal conflict because their own personal goal orientation does not fit with the goal that is experimentally induced. Two groups of learners are likely to face a mismatch and, hence, to experience internal conflict: (a) learners who personally value extrinsic goals over intrinsic goals and are placed in an intrinsic goal condition, and (b) learners who personally value intrinsic goals over extrinsic goals and are placed in an extrinsic goal condition. The experience of internal conflict might result in a less concentrated and less task-involved approach to the learning activity and, hence, help to explain why the mismatch, versus the match, conditions should undermine performance and persistence.

In addition to examining whether a match between one's personal goal orientation and the goal-framing condition yields more optimal learning, we also examined whether being placed in an experimental goal-framing condition that matches with one's spontaneous perception of the learning activity promotes optimal learning. Specifically, herein we suggest that there exists considerable variation in the type of goals people might want to attain through the same activity. Whereas some individuals perceive an activity (e.g., exercising) as serving the attainment of an intrinsic goal (e.g., health), others might perceive the same activity as serving the attainment of an extrinsic goal (e.g., physical appearance). Therefore, we examined whether the effect of experimental intrinsic versus extrinsic goal framing would also hold for individuals who perceived the activity as serving an extrinsic goal. This is an important question, as it might be argued that most of the topics (e.g., healthy lifestyles, recycling) that participants learned about in previous studies on intrinsic versus extrinsic goal framing (e.g., Vansteenkiste, Simons, Lens, Sheldon, & Deci, 2004; Vansteenkiste, Simons, et al., 2005) had, on average, a rather intrinsic goal character. Hence, the observed positive effects of intrinsic goal framing when participants learned about these topics might have been due to the match between the induced intrinsic goal and the spontaneous perception of the activity as serving an intrinsic goal. The present study aimed to shed more light on this possible confound by directly examining whether the match between one's personal perception of the activity as serving an intrinsic or an extrinsic goal and the experimentally induced intrinsic versus extrinsic goal would promote learning, performance, and persistence.

### The Present Research

The present experimental field study aimed to further examine the conflicting hypotheses that can be derived from SDT and the match perspective. Participants in the current project were fifth- and sixth-grade children who learned more about a prosocial organization that is very well known in Flanders (Belgium)—that is, the Father Damian Foundation. This foundation financially supports individuals with tuberculosis. Children in the intrinsic goal condition were told that reading about and supporting the Father Damian Foundation could be important to help patients with tuberculosis (i.e., community contribution), whereas partici-

pants in the extrinsic goal condition were told that reading about and supporting the Father Damian Foundation could be important to make a good impression on their peers, parents, and teachers (i.e., social recognition).

One week prior to their participation in the field experiment, children provided answers to two sets of questions. First, they indicated to what extent they personally valued the intrinsic goal of community contribution and the extrinsic goal of social recognition. Second, they indicated whether, if they were asked to participate in activities that support the Father Damian Foundation, they would do so to make a good impression on others and to gain social recognition (extrinsic goal) or to help people with tuberculosis (intrinsic goal). Thus, prior to their participation in the actual experiment, children indicated whether they saw a potential engagement in the Father Damian Foundation, which was also the topic they would learn about during the experimental phase, as serving the attainment of an intrinsic or an extrinsic goal.

One week after we assessed participants' personal intrinsic versus extrinsic goal orientation and their intrinsic versus extrinsic goal perception of the activity, children were randomly assigned to an intrinsic or extrinsic goal-framing condition that either matched or mismatched their personal goal orientation and their personal task perception. Because the intrinsic and extrinsic goals prevailing in the environment were not subjectively assessed but instead were experimentally induced, the present research allowed for a direct examination of the effect of an objective person-environment match (Ostroff et al., 2005).

Dependent variables in the current project included the assessment of participants' autonomous motivation for engaging in the learning activity as well as their graded performance and free-choice persistence. *Autonomous motivation* refers to a willing or volitional engagement in learning, because the learning activity is perceived as interesting and enjoyable (intrinsic motivation) and as personally meaningful (identified motivation). Two types of performance were assessed—that is, conceptual learning, which requires deep and thoughtful processing of information and a more creative and integrative solution, and rote learning, which only requires a superficial engagement in the learning and has a more straightforward or rote path to the solution (literal memorization of factual information is sufficient; Entwistle & Entwistle, 1991; Grolnick & Ryan, 1987). Although past research has shown that extrinsic goal framing yields a debilitating effect on conceptual learning, such negative effects were not observed for rote learning (Vansteenkiste et al., 2005). Presumably, extrinsic goal framing results in an attentional shift away from the activity at hand, which precludes a thoughtful elaboration of the learning material, which is necessary for conceptual learning to take place.

The following three hypotheses were tested. First, on the basis of SDT, it was expected that intrinsic vs. extrinsic goal framing would predict more autonomous motivation, more conceptual (but not rote) learning, and more persistence for all learners—that is, for both intrinsic and extrinsic goal-oriented individuals. Second, on the basis of the match perspective, it was examined whether intrinsic goal-oriented individuals would benefit from intrinsic goal framing (i.e., match) and whether their learning would be undermined in the extrinsic goal condition (i.e., mismatch). Similarly, from this perspective, it can be anticipated that extrinsic goal-oriented individuals should benefit from extrinsic goal framing (i.e., match), whereas their learning should be forestalled in the

intrinsic goal condition (i.e., mismatch). Technically speaking, we examined whether the main effect of intrinsic versus extrinsic goal framing would be moderated by participants' personal intrinsic versus extrinsic goal orientation (i.e., interaction effect).

Third, on the basis of the match perspective, it was examined whether participants who saw the activity as serving an intrinsic goal would benefit from intrinsic goal framing (i.e., match), whereas their learning would be undermined in the extrinsic goal framing condition (i.e., mismatch). Similarly, from this perspective, it was expected that participants who saw the activity as serving an extrinsic goal would display more optimal learning when placed in the extrinsic goal framing condition (i.e., match), whereas their learning would be undermined in the intrinsic goal framing condition (i.e., mismatch). Accordingly, we examined whether the predicted main effect of contextual intrinsic versus extrinsic goal framing would be moderated by individuals' perception of the activity as serving an extrinsic or an intrinsic goal.

## Method

### *Participants and Procedure*

Seventy female and 68 male fifth- and sixth-grade children ( $N = 138$ ) participated in the study. In a first stage, which took place 1 week prior to the actual experiment, participants filled out questionnaires assessing their personal intrinsic versus extrinsic goal orientations and their perception of the intrinsic versus extrinsic goal character of the activity they would participate in about 1 week later (see below). The second stage took place during a religious meeting—preparing Roman Catholic children for their confirmation—in which participants were given a text about the Father Damian Foundation that they would have to read anyway.

The study took place in schools that are located in the town where Father Damian was born. Father Damian is a very well-known and popular public figure in this neighborhood, and several activities are organized yearly in this area to support the foundation and to remember Father Damian. For this reason, it is very normal that children at a relatively young age learn more about Father Damian and the Father Damian Foundation. The present experiment took place at the time the Damian campaign was organized.

Within each class, children were randomly assigned to an intrinsic or an extrinsic goal condition (cell sample sizes of 68 and 70, respectively) and read an instruction sheet (in Dutch) prior to studying the Father Damian text. We made sure that instruction sheets were of similar length so that participants would be unaware that they had received different instructions. The instruction sheets were turned in at the end of the session, after the children had written their names on them. The instructions included one of two different goal inductions for the forthcoming learning task. In the intrinsic going-framing condition, the children read that by learning more about the Father Damian Foundation, they could learn how to help individuals with tuberculosis (i.e., “Doing your best to read the text about the Father Damian Foundation might help you to know more about how you could help people with tuberculosis. By supporting the Father Damian Foundation you can help to save the lives of tuberculosis patients”), which constituted the intrinsic goal of community contribution (Kasser & Ryan, 1996). In the extrinsic goal-framing condition, they read that learning more

about and supporting the Father Damian Foundation would help them to attain the goal of being admired by others (i.e., “Doing your best to read the text about the Father Damian Foundation might help you to collect a lot of money and hence be admired by others. Thus, supporting the Father Damian Foundation is important to gain the social recognition of others”), which reflected the extrinsic goal of social recognition (Kasser & Ryan, 1996).

After studying the text, participants completed a questionnaire that assessed their degree of autonomous motivation for reading the text. Immediately following the completion of this questionnaire, participants were tested on their knowledge concerning the text (20 min). Subsequently, they were told that they could take home a comic book (i.e., drawing) about the Father Damian Foundation if they wanted to.

### *Measures*

*Personal intrinsic and extrinsic goal orientation.* Participants' intrinsic and extrinsic goal orientations are typically assessed with Kasser and Ryan's (1996) Aspiration Index. In previous research among Dutch-speaking university (Vansteenkiste, Duriez, et al., 2006) and high school students (Duriez, Vansteenkiste, Soenens, & De Witte, 2007), we have successfully developed a shortened Dutch version of this questionnaire. In the current study, participants filled out an adapted (i.e., simplified) child version of this shortened Dutch version of the Aspiration Index. They recorded how much they valued both types of goals by circling a number on a 5-point Likert scale ranging from 1 (*not important at all*) to 5 (*very important*). We only used the data for the intrinsic goal of community contribution (four items) and the extrinsic goal of social recognition (four items), as these represent the two goals that were manipulated in the present research.<sup>2</sup>

An exploratory factor analysis using promax rotation indicated that two factors needed to be retained (eigenvalues = 3.52 and 2.73), explaining 78% of the variance across the four community contribution items (e.g., “Helping other people”) and the four social recognition items (e.g., “I will be admired by other people”). Each of the items had a minimal loading of .34. We constructed social recognition and community contribution scores by averaging the social recognition and community contribution items, respectively. Internal consistencies of the community contribution and social recognition scores were .81 and .94, respectively. These analyses provide evidence for the structure of our goal measure and indicate that children's personal valuation of community contribution and social recognition can be reliably measured.

*Intrinsic and extrinsic task perception.* Intrinsic and extrinsic task perception were assessed with two 1-item measures. Partici-

<sup>2</sup> We believe that only using the goals of community contribution and social recognition, instead of the full Intrinsic and Extrinsic Goals scales, allows for a more accurate testing of the match hypothesis. This is because the match between the personally held goals (e.g., community contribution or social recognition) and the contextually promoted goal (e.g., community contribution or social recognition) would be strongest if one only retained the intrinsic goal of community contribution and the extrinsic goal of social recognition. The inclusion of the other intrinsic and extrinsic goals in the personal goal orientation measure would result in a poorer match between the personally held and contextually promoted goals and, as a result, would represent a methodologically weaker way of testing the match hypothesis.

pants were asked how important they found it to support the Father Damian Foundation to achieve the intrinsic goal of community contribution (i.e., “I prefer to support the Father Damian Project because it gives me the opportunity to help other people”) or the extrinsic goal of social recognition (i.e., “I prefer to support the Father Damian Project because of the good impression it makes on other people”). We focused on these two goals only because they represent the two goals that were manipulated during the actual experiment. On both items, participants indicated their agreement on a 10-point Likert scale that varied from 1 (*completely disagree*) to 10 (*completely agree*).

*Autonomous motivation.* Consistent with SDT and previous experimental studies among children (Vansteenkiste et al., 2005), autonomous motivation was measured by the extent to which participants found the reading material enjoyable and interesting (e.g., “I read the text because I found it very interesting”; intrinsic motivation; four items;  $\alpha = .91$ ) and personally relevant and meaningful (e.g., “I read this text because the content is personally meaningful to me”; identified regulation; four items;  $\alpha = .81$ ). Participants indicated their agreement with each of the items by circling a number between 1 (*completely disagree*) and 5 (*completely agree*). As in previous research (e.g., Vansteenkiste, Lens, Dewitte, De Witte, & Deci, 2004), we created a composite score of autonomous motivation by averaging the scores on these two subscales ( $\alpha = .82$ ).

*Test performance.* Two aspects of learning were assessed—that is, conceptual and rote learning. Five short questions tapped rote learning. To answer these questions, children needed to fill in one single word that was specifically mentioned in the text on Father Damian. As a result, scale scores for rote learning varied between 1 and 5. Concerning conceptual learning, the children were given three problems, which were scored on a scale varying from 1 (*very bad*) to 15 (*very good*). The first two conceptual problems were as follows: “Provide three examples that illustrate that Father Damian is a ‘stubborn stayer’” (4 points), and “Provide three reasons for the beatification of Father Damian” (3 points). The third problem was a crossword puzzle, which required children to fill in eight words (8 points). Each of the crossword questions tapped a deeper understanding of the learning material, as the answer to the question was not mentioned in the text but needed to be derived from it by meaningful linking of different pieces of information. These problems were created by the teacher and had been used in previous years to test children’s knowledge with respect to Father Damian. Therefore, the test was ecologically valid, and the children would have had to respond to the questions even if they had not been involved in the study (see Vansteenkiste et al., 2005, for a similar methodology). The regular teacher and one independent and trained rater, who were both blind to the nature of the study, determined whether the answers to these rote and conceptual learning questions were correct (1) or incorrect (0). There was perfect agreement between the raters scoring each question, as indexed by a perfect Pearson correlation between the two sets of rating scores.

*Persistence.* Participants were offered the opportunity to take home a comic book on Father Damian so that they could learn more about him and his foundation. The instructor registered who took home a comic book. In total, 75 participants (54%) did so. This constitutes a behavioral measure of free-choice persistence, as

it represents the tendency to display continued interest in the learning material once the learning task is terminated.

Results

Preliminary Analyses

One-sample *t* testing,  $t(137) = 7.90, p < .001$  indicated that, as a whole, the children valued the intrinsic goal of community contribution ( $M = 3.34, SD = 1.11$ ) more strongly than the extrinsic goal of social recognition ( $M = 2.43, SD = 0.88$ ), a finding that replicates previous work on intrinsic versus extrinsic goals among undergraduate students (e.g., Grouzet et al., 2006). To examine what percentage of children valued social recognition over community contribution and what percentage of children valued community contribution over social recognition, we subtracted participants’ social recognition score from their community contribution score. Then we dichotomized this difference measure by assigning all participants who had a negative difference score (indicating that they valued social recognition over community contribution) a score of  $-1$  and by assigning all participants who had a positive difference score (indicating that they valued community contribution over social recognition) a score of  $1$ . In total, 30% of the participants ( $n = 41$ ) valued social recognition over community contribution, and 70% of the participants ( $n = 97$ ) valued community contribution over social recognition. In the remainder of this article, the former group is referred to as the *extrinsic goal-oriented participants*, whereas the latter group is referred to as the *intrinsic goal-oriented participants*.

Next, we created four different groups by crossing contextual intrinsic versus extrinsic goal framing with the dichotomized personal intrinsic versus extrinsic goal orientation measure. Then we performed a chi-square test on the percentages of intrinsic and extrinsic goal-oriented individuals who were placed in the intrinsic and extrinsic goal-framing conditions. The purpose of this analysis was to examine whether intrinsic and extrinsic goal-oriented participants were equally distributed over the intrinsic and extrinsic goal-framing conditions. The percentages and exact cell sizes can be found in Table 1. The chi-square test turned out to be nonsignificant,  $\chi^2(1, N = 138) = 0.85$ , indicating that the intrinsic and extrinsic goal-framing conditions consisted of an equal percentage of intrinsic and extrinsic goal-oriented individuals.

Table 1  
Frequencies and Cell Sizes per Condition (Contextual Goal Framing × Personal Goal Orientation)

Contextual goal framing	Personal goal orientation		Row total
	Intrinsic	Extrinsic	
Intrinsic			
%	71	29	51

A similar set of analyses was performed on participants' intrinsic versus extrinsic task perception. One-sample  $t$  testing,  $t(137) = 8.13$ ,  $p < .001$ , indicated that, on average, children were more likely to see their participation in the Father Damian Foundation as serving the intrinsic goal of community contribution ( $M = 6.54$ ,  $SD = 1.80$ ) than as serving the extrinsic goal of social recognition ( $M = 4.01$ ,  $SD = 2.23$ ). To examine what percentage of children perceived participation in the Father Damian Foundation as more strongly serving community contribution than social recognition and what percentage of children saw their participation as more strongly serving social recognition than community contribution, we subtracted the former scale from the latter. Then we dichotomized this continuous difference scale by assigning a score of  $-1$  if the participants had a negative difference score (indicating that they saw their participation as more strongly serving social recognition than community contribution) and assigning a score of  $1$  if participants had a positive difference score (indicating that they saw their participation as more strongly serving community contribution than social recognition). In total, 33% of the participants ( $n = 46$ ) saw their participation in the Father Damian Foundation as serving social recognition more strongly than community contribution, whereas 67% of the participants ( $n = 92$ ) saw their participation as more strongly serving community contribution.

Next, we created four groups by crossing intrinsic versus extrinsic goal framing with the constructed dichotomous intrinsic versus extrinsic task perception measure. Percentages and exact numbers of participants per group can be found in Table 2. Again, we performed a chi-square test with the purpose of examining whether individuals who perceived the task as intrinsically or extrinsically goal oriented were equally distributed across the two experimental conditions. The chi-square test turned out to be nonsignificant,  $\chi^2(1, N = 138) = 0.72$ , indicating that both groups of participants were equally distributed over the intrinsic and extrinsic goal-framing conditions.

In sum, these preliminary analyses indicated (a) that the sample of participants was quite heterogeneous in terms of both its intrinsic-extrinsic goal profile and its perception of the Father Damian Foundation as serving an intrinsic or extrinsic goal; (b) that the extrinsic and intrinsic goal-oriented participants, as well as the participants who saw the Father Damian Foundation as primarily serving an intrinsic goal or an extrinsic goal, were equally

distributed across the two experimental conditions; and (c) that each of the created groups, which represented a combination of contextual goal framing with either participants' personal goal orientation or their task perception, consisted of a sufficiently large number of participants (more than 20). Thus, these preliminary analyses indicated that we could proceed with the testing of our primary hypotheses.

Finally, to examine possible gender effects, we performed an independent-sample  $t$  test including autonomous motivation, performance, and persistence as dependent variables. Girls ( $M = 2.94$ ,  $SD = 0.48$ ) were found to be more autonomously motivated than boys ( $M = 2.75$ ,  $SD = 0.51$ ),  $t(136) = 2.28$ ,  $p < .05$ , but no gender differences were found with respect to conceptual learning, rote learning, and persistence. Hence, we controlled for gender effects in subsequent analyses when predicting autonomous motivation.

### Primary Analyses

The means and standard deviations for all variables across conditions, as well as the correlations between each pair of variables, are presented in Table 3. We examined our central hypotheses by performing two sets of regression analyses, one involving the difference score of intrinsic versus extrinsic goal orientations as a moderator, and one involving the difference score of intrinsic versus extrinsic activity perceptions as a moderator of experimental intrinsic versus extrinsic goal framing. We conducted multiple regression analyses to examine the effects on the continuous outcomes of autonomous motivation and both types of performance, but we made use of logistic regression analyses to examine the effects on the categorical outcome of persistence. In these primary analyses, we preferred to use the continuous (instead of the dichotomous) difference measures of intrinsic versus extrinsic goal orientations and intrinsic versus extrinsic goal task perception to increase statistical power.

In the first series of regressions, experimental intrinsic versus extrinsic goal framing, the continuous difference measure of intrinsic versus extrinsic goal orientation and the goal framing  $\times$  goal orientation interaction measure were entered in the regression equation. Experimental goal framing and goal orientation were centered, and the interaction term was calculated as the product of these centered scores. Multiple regression analyses indicated that experimental intrinsic, relative to extrinsic, goal framing positively predicted autonomous motivation ( $\beta = .43$ ,  $p < .001$ ) and conceptual learning ( $\beta = .31$ ,  $p < .001$ ) but was unrelated to rote learning ( $\beta = .13$ ,  $ns$ ). Intrinsic versus extrinsic goal orientation positively predicted autonomous motivation ( $\beta = .17$ ,  $p < .05$ ) but was unrelated to conceptual learning ( $\beta = .01$ ,  $ns$ ) and rote learning ( $\beta = -.05$ ,  $ns$ ).

On the basis of the match perspective, the main effect of experimental goal framing should be altered depending on individuals' personal goal orientations. However, the interactions between experimental goal framing and goal orientation in the prediction of autonomous motivation ( $\beta = -.08$ ,  $ns$ ), conceptual learning ( $\beta = -.01$ ,  $ns$ ), and rote learning ( $\beta = .06$ ,  $ns$ ) were not significant. Concerning persistence, a logistic regression analysis pointed out that the three predictors yielded an overall effect on persistence (dummy coded as lack of persistence = 0 and persistence = 1),  $\chi^2(3, N = 138) = 25.58$ ,  $p < .001$ . Persistence was

significantly predicted by placement in the experimental intrinsic goal-framing condition (odds ratio [OR] = 0.17,  $p < .001$ ) but not by the personal goal orientation measure (OR = 1.22, *ns*) nor by the interaction between experimental goal framing and the personal goal orientation measure (OR = 0.94, *ns*). Together, the predictors explained between 2% and 26% of the variance in the outcomes.

In a second set of regressions, the three outcomes were regressed on experimental intrinsic versus extrinsic goal framing, the continuous difference measure of intrinsic versus extrinsic activity perception, and the interaction between experimental goal framing and activity perception. Concerning autonomous motivation and performance outcomes, multiple regression analyses indicated that experimental intrinsic versus extrinsic goal framing positively predicted autonomous motivation ( $\beta = .42$ ,  $p < .001$ ) and conceptual learning ( $\beta = .34$ ,  $p < .001$ ) but was unrelated to rote learning ( $\beta = .09$ ). Intrinsic versus extrinsic activity perception was unrelated to autonomous motivation ( $\beta = .11$ , *ns*), conceptual learning ( $\beta = .10$ , *ns*), and rote learning ( $\beta = .13$ , *ns*). Most important, the interaction between experimental goal framing and activity perception did not reach significance (autonomous motivation,  $\beta = .14$ , *ns*; conceptual learning,  $\beta = -.05$ , *ns*; and rote learning,  $\beta = .05$ , *ns*). Concerning persistence, a logistic regression analysis indicated that the three predictors yielded an overall effect,  $\chi^2(3, N = 138) = 30.69$ ,  $p < .001$ . Persistence was significantly predicted by placement in the experimental intrinsic goal framing condition (OR = 0.14,  $p < .001$ ) and by the presence of an intrinsic activity perception (OR = 1.15,  $p < .01$ ) but not by the interaction between experimental goal framing and the activity perception measure (OR = 0.93, *ns*). Together, the predictors explained between 4% and 27% of the variance in the outcomes.<sup>3</sup>

## Discussion

The present research examined conflicting hypotheses derived from SDT and the match perspective regarding the impact of intrinsic versus extrinsic goal framing on learning and performance. This research extends previous work in this area by using an experimental instead of a correlational design, by focusing on learning and performance instead of well-being as outcomes, and by examining the possible moderating role of two types of individual-differences variables (i.e., intrinsic vs. extrinsic goal orientation and intrinsic vs. extrinsic activity perception) in the relation between intrinsic versus extrinsic goal framing and learning and performance. Several important findings emerged.

Several previous studies among fifth- to sixth-grade children, high school students, and college students have shown that the experimental induction of intrinsic goals promotes better conceptual learning and persistence compared to the induction of extrinsic goals (see Vansteenkiste, Lens, & Deci, 2006). The present research fully replicated previous studies by showing that extrinsic, relative to intrinsic, goal framing undermined participants' self-reported task enjoyment and personal valuation of the activity (i.e., autonomous motivation) and forestalled their conceptual performance and persistence. The reason for these effects is probably that inducing an extrinsic goal creates an outward orientation by drawing individuals' attention toward the external signs of worth. This attentional shift precludes the possibility of task-absorbed engagement in the activity, so that participants fail to enjoy the learning activity and perform less well (Vansteenkiste, Lens, & Deci, 2006). As in previous experimental work (Vansteenkiste et al., 2005), the negative effect of extrinsic goal framing did not emerge for rote learning. Apparently, extrinsic goal framing prompts some motivated learning; however, the learning activity is approached in a more rigid and narrow-minded fashion, because the learning is primarily oriented toward attaining the extrinsic goals. Such a rigid and restricted approach is sufficient to promote memorization of learning material but interferes with an in-depth processing of the contents.

Beyond replicating past results, the main contribution of the present work was to examine whether the effects of contextual goal framing depended on participants' own goal preferences. Vansteenkiste, Simons, Lens, Sheldon, and Deci (2004) found that extrinsic (vs. intrinsic) goal framing undermined optimal learning among a group of business students, but they did not include assessments of individuals' own goal orientations prior to participation in the experiment. As such, the authors had no opportunity to directly examine whether goal framing interacted with personal goal orientations. In particular, research to date has not directly tested the possibility that the observed negative effects of extrinsic goal framing would be reversed for extrinsic goal-oriented indi-

<sup>3</sup> As recommended by one of the anonymous reviewers, we conducted a power analysis. A post hoc power analysis indicated that with the current sample size of 138,  $\alpha = .05$ , three used predictors, and  $R^2 = .20$ , the current set of regression analyses yielded sufficient power (i.e., 1.00) to detect significant effects. An a priori power analysis indicated that with a desired power of .80, an alpha level of .05, an estimated effect size of .25, and a total of three predictors, we would need to sample at least 48 participants. The current sample size meets this requirement amply.

viduals, as would be predicted by the match perspective. The present research addressed exactly this question.

On average, participants in the present sample were found to more strongly value the intrinsic goal of community contribution than the extrinsic goal of social recognition, a finding that is in line with various previous studies (e.g., Grouzet et al., 2006). In spite of this, 30% of the present sample attached higher importance to social recognition than to community contribution, which suggests that the current sample was relatively heterogeneous in terms of its intrinsic–extrinsic goal profile. Furthermore, the extrinsic goal-oriented individuals appeared to be equally distributed across the intrinsic and extrinsic goal-framing conditions, and, thus, participants appeared to be randomly dispersed across the experimental conditions. Interaction analyses between contextual goal framing and personal goal orientation indicated that the effect of contextual intrinsic versus extrinsic goal framing did not depend on participants' personal intrinsic versus extrinsic goal orientation. Thus, the match perspective could not be confirmed, as both intrinsic and extrinsic goal-oriented individuals benefited from being placed in an intrinsic goal condition. Presumably, the shift in attention that we caused by inducing an extrinsic goal negatively affected both intrinsic and extrinsic goal-oriented individuals. Referring to an extrinsic goal elicits self-worth concerns and distracts all participants' attention from the activity at hand, which undermines optimal learning (Vansteenkiste, Lens, & Deci, 2006). In contrast, learning in the service of intrinsic goals is more consistent with people's basic psychological needs, which should promote more optimal learning for all individuals (Deci & Ryan, 2000; Kasser, 2002).

The match perspective was also tested in a second way. We suggest that there exists considerable variability in the type of goals the same activity might serve. Whereas some individuals might perceive an activity as serving the attainment of intrinsic goals, other individuals would see the same activity as a means toward extrinsic goal attainment. A possible confound in previous work on intrinsic versus extrinsic goal framing is that the selected activities (e.g., reading a text on recycling) might, on average, be perceived as serving an intrinsic goal. When individuals are subsequently instructed that the activity serves an intrinsic goal, they find themselves in a match situation, whereas individuals who are told that the activity serves an extrinsic goal find themselves in a mismatch situation. The induced extrinsic goal might even be seen as meaningless and the instructions as unbelievable, because they conflict with participants' spontaneous goal perception of the activity.

To eliminate this possible confound, we obtained direct assessments of the type of goals individuals pursued through supporting the Father Damian Foundation, the topic they would read about during the experimental phase. Although children saw the activity, on average, as standing more strongly in the service of intrinsic than extrinsic goal attainment, there was substantial variation in their perceptions. That is, one third of the children saw the activity as instrumental for extrinsic goal attainment (i.e., social recognition), whereas the other two thirds saw the activity as instrumental for intrinsic goal attainment (i.e., community contribution). We found that the effect of intrinsic versus extrinsic goal framing was not altered for individuals who spontaneously saw the activity as serving an extrinsic goal. All individuals, regardless of their activity perception, displayed more optimal learning in the intrinsic, compared to the extrinsic, goal-framing condition.

Another set of findings that deserves some discussion is the observation that individuals' intrinsic versus extrinsic goal profiles and intrinsic versus extrinsic activity perception had smaller effects on their motivation, learning, and performance compared to the effects of contextual goal framing. Although these results need to be replicated in future research, we provide two explanations. First, the individual goal measures were assessed 1 week prior to children's participation in the experiment, whereas children read the instructions on intrinsic versus extrinsic goal framing a few minutes before reading the text. Because of this different time lag, it seems logical that contextual goal framing yielded stronger effects compared to the two individual-differences measures.

A second interpretation deals with the level of generality at which the independent variables can be situated. That is, within the hierarchical model of motivation (Vallerand, 1997), a global (i.e., personality), a domain-bounded (i.e., in a particular life domain), and a situational (i.e., for a specific task) level of motivation are distinguished. Clearly, the present study examined participants' learning and performance on a specific task—that is, at the situational level of motivation. Whereas participants' intrinsic and extrinsic goal profiles reflect their global endorsement of goals, contextual goal framing represents a manipulation at the situational level, because the presented goals are directly linked to the learning activity itself. Hence, it seems logical that contextual goal framing is a better predictor of situation-bounded outcomes than participants' goal profiles, because the former are situated at a similar level of motivation, whereas the latter are not (see also Roberts & Pomerantz, 2004, for a similar reasoning).

Does the current set of results imply that all types of goal-match situations will invariantly fail to predict optimal performance? We do not think so. Researchers have focused on very different types of goals and psychological constructs to examine the match hypothesis (see Amiot et al., 2006; Bianco et al., 2003; Harackiewicz & Elliot, 1998). The present research differs from that work because it focuses on the concepts of intrinsic versus extrinsic goals. To address the question of whether particular goals will promote optimal functioning, SDT suggests that researchers evaluate the functional significance of these goals by asking how they are dynamically related to basic psychological need satisfaction. If the pursuit or induction of particular goals fails to promote basic need satisfaction, a match situation is unlikely to override the negative effects associated with thwarted need satisfaction. Because extrinsic goal induction is, on average, unrelated or even negatively related to basic need satisfaction, these goals should result in diminished learning, even when individuals strongly value these goals, as convincingly shown in the present research. SDT's position regarding the motivational impact of goals also implies that if particular goals cannot be meaningfully tied to basic need satisfaction, placing the individual in a match situation might predict more optimal functioning. Overall, we believe that more research is needed to carefully examine whether the match hypothesis holds for particular goals, whereas it does not for other types of goals.

### *Practical Implications*

Previous research (e.g., Kasser & Ahuvia, 2002; Sagiv & Schwartz, 2000) investigated whether extrinsically oriented individuals benefit psychologically if their personal goals match with the goals emphasized in their environment. Accordingly, these studies focused on the question of whether a person's goals should

match with the environmentally promoted goals to predict psychological well-being (i.e., person–environment match). The present study asked a different question: Do socializing agents need to adjust their goal framing in accordance with the goal profiles of the individuals who need to be motivated? Put differently, does the environment need to be accommodated to the persons who are entering it (environment–person match)? If this were true, it would imply that socializing agents first need to gain insight into individuals' personal goal orientations and, subsequently, need to use individualized goal-framing instructions that match the person's goal preference to motivate learning. This seems an extremely difficult task. Luckily, the present experiment indicates that socializing agents' motivational task is much easier: It suffices to induce intrinsic goals when one is trying to promote optimal learning, even if individuals ascribe high importance to extrinsic goals themselves.

Of course, there might be a few boundary conditions to this goal framing effect that could be more thoroughly examined in future research. First, consistent with previous goal research (Locke & Latham, 1990, 2002), we suggest that a specific, instead of a vague, intrinsic goal is more likely to promote optimal learning (see also Vansteenkiste, Simons, Soenens, & Lens, 2004). Second, the induced intrinsic goal needs to be realistically and meaningfully connected to the learning activity, so that learners accept the provided intrinsic goal. Past research has shown that providing a goal that is not accepted by participants does not yield the same performance benefits (Locke & Latham, 1990). Third, although extrinsic goal framing undermines deep-level learning, the current study shows that extrinsic goal framing predicts a similar extent of superficial and shallow learning as intrinsic goal framing (Vansteenkiste et al., 2005).

### Limitations and Future Research

The current project contained a number of shortcomings that might be overcome in future research. First, only one single intrinsic goal and one single extrinsic goal were manipulated. In future studies, researchers might want to examine whether manipulation of other extrinsic goals (e.g., physical appearance, financial success) promotes or undermines optimal learning among individuals who attach importance to these extrinsic goals. Second, it would be interesting to develop a measure of experienced goal conflict versus goal congruence as a check on whether individuals placed in a mismatch condition effectively experience goal conflict, while those placed in a match condition experience goal congruence. Third, future research might sample extrinsically oriented individuals who are older (e.g., business college students) than the ones who participated in the current project to examine whether the match hypothesis could be confirmed (or not) among these older age groups. Finally, the current results might also be examined in different domains from learning and education, including sports and exercising, work, and cross-cultural research. For instance, it would be interesting to examine whether the pursuit of extrinsic goals yields different effects depending on whether one perceives one's coach, one's manager, the organization, or even the culture at large as promoting and reinforcing such goals.

### Conclusion

The results of the present study indicate that framing a learning activity in terms of the attainment of an extrinsic rather than an intrinsic goal undermined task enjoyment, personal valuation of a learning activity, conceptual learning, and persistence, irrespective of individuals' own intrinsic and extrinsic goals or their intrinsic and extrinsic task perception. Hence, these results suggest that instructors, teachers, and other socializing agents might do well to promote intrinsic goals and might downplay the promotion of extrinsic goals to motivate conceptual learning and performance, even for individuals who ascribe high importance to such extrinsic goals.

University of Wisconsin—Madison

The research presented in this article integrates 3 theoretical perspectives in the field of motivation: expectancy-value, achievement goals, and interest. The authors examined the antecedents (initial interest, achievement goals) and consequences (interest, performance) of task value judgments in 2 learning contexts: a college classroom and a high school sports camp. The pattern of findings was consistent across both learning contexts. Initial interest and mastery goals predicted subsequent interest, and task values mediated these relationships. Performance-approach goals and utility value predicted actual performance as indexed by final course grade (classroom) and coach ratings of performance (sports camp). Implications for theories of motivation are discussed.

*Keywords:* utility value, achievement goals, interest, expectancy value, performance

The definition of optimal motivation . . . is motivation that produces optimum intellectual development. Though optimum intellectual development is the ultimate goal, progress toward it is assessed in terms of motivation. (Nicholls, 1979, p. 1072)

As Nicholls (1979) asserted, motivation and achievement are inherently connected. An understanding of the motivational dynamics at work in achievement settings will therefore allow researchers and educators to better understand how to promote learning. Motivation is defined here as a motive (e.g., wish, intention, drive) to engage in a specific activity (Austin & Vancouver, 1996; Schiefele, 1999; Weiner, 1985), and can be conceptualized as a behavioral antecedent, a process experienced during task engagement, and as an outcome. Utilizing this multifaceted conceptualization of motivation enables an integration of three distinct, yet overlapping, theoretical perspectives: expectancy-value (Eccles, 2005), achievement goal (Dweck, 1986; Nicholls, 1984), and interest theory (Hidi & Renninger, 2006). These three per-

spectives allow researchers to understand motivational dynamics in a way that any one single perspective may not completely capture.

Interest in activities has been considered to be one of the central components of motivation and motivated behavior (Deci & Ryan, 1985; Dewey, 1913; Schiefele, 1991). One way to develop interest in activities is to find meaning and value in those activities (Hidi & Renninger, 2006; Renninger & Hidi, 2002). Achievement goals and initial interest can predispose individuals to find value in educational activities (Hidi & Harackiewicz, 2000; Pintrich, 2003; Wigfield & Eccles, 2002). Thus, we propose a model of motivation wherein achievement goals and initial interest lead to the perception of task value, which then promotes the development of subsequent interest and learning. In the present article, we examine the antecedents and consequences of task value judgments in two learning contexts: a college classroom and a high school sports camp.

## Task Values

Research from the expectancy-value perspective has examined the values that individuals perceive when engaging in tasks, and how these task values are related to subsequent achievement choices. Eccles and her colleagues (Eccles et al., 1983; see Eccles, 2005, for a review) have identified several types of task value that are important in predicting motivation and achievement, in addition to the well-documented effects of success expectancies (Bandura, 1997; Pintrich & Schunk, 2002). Two of these task values are utility and intrinsic value. Tasks with utility value are important because they are useful and relevant beyond the immediate situation, for other tasks or aspects of a person's life. Tasks with intrinsic value are important to the individual because they are enjoyable and fun. Individuals can discover and appreciate the value of activities through interaction and experience. Perceiving utility and/or intrinsic value in tasks has been associated with motivation and interest in activities. For example, both intrinsic

and utility value have been found to predict motivational outcomes such as course enrollment decisions (Harackiewicz, Durik, Barron, Linnenbrink-Garcia, & Tauer, 2008; Meece, Wigfield, & Eccles, 1990; Updegraff, Eccles, Barber, & O'Brien, 1996; Wigfield, 1994), self-reported effort in science classes (Cole, Bergin, & Whittaker, 2006; Mac Iver, Stipek, & Daniels, 1991), intentions to continue a school-based running program (Xiang, Chen, & Bruene, 2005), amount of free time spent on sports (Eccles & Harold, 1991), and classroom interest (Durik, 2003).

Whereas both intrinsic and utility task values have been linked to motivation, utility value may be uniquely related to achievement. For example, Simons, Dewitte, and Lens (2003) found that highlighting the usefulness of an activity—by telling participants how it could help them achieve their future goals—increased persistence and performance in a physical education class. Bong (2001b) found that the perceived usefulness of a course predicted self-efficacy in the course, which in turn predicted exam performance. Malka and Covington (2005) found that the relevance of school work to students' future goals (i.e., perceived instrumentality) predicted classroom performance. These studies indicate that there is a relationship between perceiving utility in a task and subsequent performance.

Given the role of intrinsic and utility value in predicting interest and performance, it is essential to understand how individuals come to perceive tasks as intrinsically valuable and useful. The expectancy-value model proposes that goals lead to task values, which are considered to be the more proximal predictors of achievement choices (Eccles et al., 1983; Wigfield & Eccles, 1992, 2002). A large body of research suggests that the achievement goals that students and athletes pursue serve to orient them to tasks (Duda, 1995), influence their cognitive processes and effort during task engagement (Linnenbrink & Pintrich, 2000), and help them find more or less value in what they do (Pintrich, 2003; Wigfield & Eccles, 1992). For example, a student whose goal is to learn and understand course material may be more likely to experience the intrinsic value of the material and see how the course is relevant to his or her life. This enjoyment and personal connection with the material may facilitate attention, cognitive processing, effort, and subsequent interest (Hidi, 1990; Hidi & Harackiewicz, 2000).

### Achievement Goals

According to the achievement goal perspective (Ames, 1984; Dweck, 1986; Nicholls, 1984), goals are mental representations of individuals' competence strivings during achievement activities (Maehr, 1989; Shah & Kruglanski, 2000). Although different labels have been used by researchers over the years, achievement goals have been divided into two general classes: mastery and performance (Ames & Archer, 1988), while also being subdivided into approach and avoidance components (Elliot, 1999; Elliot & McGregor, 2001; Pintrich, 2000a). In this article, we will focus on approach goals because we believe that approach motivation is the most relevant for the discovery of value and development of interest. Mastery-approach goals focus on developing knowledge and learning new skills, whereas performance-approach goals focus on doing well compared with other people. Research has demonstrated that mastery-approach goals positively predict a variety of motivational variables including classroom interest (Ames & Archer, 1988; Harackiewicz, Barron, Pintrich, Elliot, &

Thrash, 2002; Lee, Sheldon, & Turban, 2003), as well as deep processing, effort, and persistence (Elliot, McGregor, & Gable, 1999; Harackiewicz, Barron, Tauer, Carter, & Elliot, 2000; Midgley, Kaplan, & Middleton, 2001; Wolters, Yu, & Pintrich, 1996). On the other hand, performance-approach goals are positively linked to academic performance (Harackiewicz, Barron, Pintrich, et al., 2002; but see Grant & Dweck, 2003).

When individuals pursue performance goals, they focus on the outcome of task engagement (i.e., success/failure) and may not become deeply engaged in the activity. In contrast, individuals who pursue mastery goals focus on learning and improvement, and are able to experience and explore the activity because they are focused on the process rather than on the product of task engagement (Dewey, 1913; Flum & Kaplan, 2005; Renninger & Hidi, 2002). This task focus may allow them to discover or experience both intrinsic and utility value, which may then motivate effort, persistence, and subsequent interest. From this perspective, achievement goals operate as a framework for the perception of task value, and perceived task value becomes the more proximal predictor of interest and performance. Experimental studies have documented the effects of mastery goals on task involvement and task interest (Senko & Harackiewicz, 2005; Zimmerman & Kitsantas, 1997; for a review, see Rawsthorne & Elliot, 1999). Other research has demonstrated that mastery-approach goals are correlated with both utility and intrinsic value (Bong, 2001a; DeBacker & Nelson, 1999; Linnenbrink, 2005; Mac Iver et al., 1991; Shim & Ryan, 2005; Simons, Dewitte, & Lens, 2004; Wigfield & Eccles, 2002; Xiang, McBride, & Bruene, 2004).

In summary, our hypothesized model suggests that mastery goals create a framework within which individuals focus on the task and perceive value in it. Perceiving both intrinsic and utility value can lead to the development of subsequent interest. Although mastery goals have not been consistently associated with achievement (Harackiewicz, Barron, Pintrich, et al., 2002), mastery goal adoption may have indirect effects on performance through perceptions of utility value. Perceived utility value may emerge from deep engagement in an activity (facilitated by a mastery goal), and may motivate attention, effort, and persistence that result in higher levels of performance.

### The Development of Interest

How does the perception of value influence the development of interest? Interest can be defined as a psychological state, for example, "being engaged, engrossed, or entirely taken up with some activity" (Dewey, 1913, p. 17), and as a process that emerges over time (Hidi & Renninger, 2006). The psychological state of interest that arises through interactions with task features, such as stimulating pictures and humor, is known as *situational interest* (Hidi, 1990). Interest that is more enduring and traitlike, and that develops and deepens over time, is known as *individual interest* (Renninger, 2000). Perceiving value in activities has been hypothesized to be a key contributor in the progression from situational to individual interest, and to the deepening of existing individual interest (Hidi & Renninger, 2006). As momentary interest in the situation is activated, an individual may come to perceive value in the activity and desire to continue pursuing the activity over time, resulting in maintained situational interest. If situational interest is maintained and an individual continues to engage in the activity

and perceive value, then individual interest may develop (emerging individual interest). Thus, perceived value may play a critical role in the beginning stages of interest development as well as in the deepening of individual interest over time.

### Integration of Motivational Perspectives

Although we have conceptualized value and interest as distinct constructs, many theorists consider value to be an integral component of interest (Dewey, 1913; Hidi & Harackiewicz, 2000; Hidi & Renninger, 2006; Krapp, 2002; Mitchell, 1993; Schiefele, 1991). We agree, but believe these constructs can be distinguished over time. In particular, we are interested in how the perception of task value early in a learning experience influences the development of subsequent interest. For example, students might find a specific lecture or reading assignment in a psychology class to be enjoyable (intrinsic value) or relevant to their lives (utility value), and this perception of value could then lead to the development of subsequent interest in psychology. In terms of Hidi and Renninger's (2006) four-phase model of interest development, perceived task values would correspond to both the triggering of situational interest and the early stages of maintained situational interest, whereas subsequent interest in psychology would correspond to the latter stages of maintained situational interest or the emergence of individual interest. This conceptualization of task values as situational interest is not inconsistent with Eccles et al.'s (1983) perspective; rather, it is simply a more specific formulation that allows us to integrate these theoretical perspectives. In the Eccles et al. (1983) model of task values, intrinsic and utility task values could be considered as more general beliefs or as situation-specific reactions to the task. In this article, we consider task values to be situation-specific predictors of subsequent interest and performance; whereas *interest* refers to more general beliefs about the activity over time. This important distinction allows us to consider perceived task value and subsequent interest as separate outcomes, and to evaluate how the emergence of value during task engagement contributes to the development of subsequent interest.

This model of interest development is supported by our previous theoretical (Hidi & Harackiewicz, 2000) and empirical (Harackiewicz et al., 2008) work, and requires that we consider the initial level of interest that students and athletes bring into learning situations. Hidi and Renninger's (2006) four-phase model of interest development outlines how interest develops and deepens in a situation depending on the value, positive affect, and knowledge experienced with an activity. Individuals who have different levels of experience and knowledge of an activity may enter a situation with different levels of initial interest. Thus, in order for us to assess the role of value in interest development, we will need to consider initial levels of interest in the activity (Hidi & Renninger, 2006; Maxwell & Cole, 2007).

The integration of achievement goal, interest, and expectancy-value models of motivation complements the previously established notion that there can be multiple pathways to optimal motivation (Barron & Harackiewicz, 2001; Harackiewicz, Barron, Pintrich, et al., 2002; Pintrich, 2000b, 2003). For example, achievement goal researchers have emphasized the importance of testing the independent and interactive effects of achievement goals on outcomes, and have identified several patterns of multiple goal effects (cf. Harackiewicz, Barron, Pintrich, et al., 2002). In

this article, we also assess the indirect effects of achievement goals through task values. This analysis complements the multiple goals perspective in that it provides additional pathways through which achievement goals might promote interest and performance. Although not exhaustive, our theoretical integration incorporates three related perspectives in which we have conducted prior research, and as such is an initial step toward theoretical synthesis. In addition, our framework is generally consistent with other motivational models, such as those that propose dual-regulation systems (Boekaerts, 2003; Boekaerts & Corno, 2005; Heckhausen, 2000; Krapp, 2002, 2005; Kuhl, 2001; Schiefele, 1991). These models suggest that behavior is regulated by both cognitive/rational and emotional/feeling subsystems, which parallels our explication of utility and intrinsic value as two components of situational interest.

### Current Research

In two studies, we investigated the predictors and consequences of task value in classroom and sports contexts. We were primarily interested in (a) the role of task value in interest development and performance, and (b) the role of achievement goals in creating a framework for the perception of task value. In Study 1, we examined college students' perceptions of task values in an introductory psychology course, as well as their achievement goals, as predictors of their subsequent interest in the topic and academic performance. In Study 2, we examined high school athletes' perceptions of task values at a summer football camp, as well as their achievement goals, as predictors of their subsequent interest and performance at camp. In both studies, we controlled for initial interest in the activity.

College classes and sports camps are similar in terms of their educational mission and definition of achievement. In both settings, there is a focus on learning: Students learn lessons, do homework, and take tests, whereas athletes learn techniques, practice and do drill work, and play competitive games. For some individuals, sports may be more interesting than academics (and vice versa), but both can involve long hours of homework and repetitive drills. Success in both domains can require the ability to practice and work through difficult or boring activities. Given these similarities, theories of achievement motivation and interest should be applicable to both domains.

There is also an important difference between sports and school that should not be overlooked, particularly in terms of interest development: Most athletes have chosen to participate in their sport, whereas students often have little or no choice in which classes they take, particularly when fulfilling academic requirements. Although the decision to take an introductory course may indicate a certain level of initial interest in the topic, most students are unlikely to have had extensive experience with the topic. The introductory course therefore provides the opportunity to examine the emergence and development of interest in its early phases (Hidi & Renninger, 2006). In contrast, athletes willing to attend a summer camp at their own expense typically have extensive experience with the sport and a well-developed interest in it. Thus, the high school summer sports camp provides the opportunity to examine the role of situational interest in deepening already well-developed interest.

## Study 1—The College Classroom

We investigated the role of task values and achievement goals in predicting subsequent interest and performance in a college classroom, controlling for initial levels of interest. On the basis of previous findings (Harackiewicz, Barron, Pintrich, et al., 2002; Wigfield & Eccles, 2002), we hypothesized that mastery goals would predict the perception of value and the development of subsequent interest in the course, and that performance-approach goals would predict course grades. Including a measure of initial interest allowed us to clarify the relationship between mastery goals, task values, and the development of subsequent interest. In addition, we hoped to explore relationships between values and performance by examining utility and intrinsic values separately. Specifically, we hypothesized that perceiving utility value in the course might also predict performance.

### Method

#### Overview

This study took place during the course of a semester at a large, midwestern university and consisted of three waves of data collection during the semester. Students' initial interest in the course topic and achievement goals were assessed on the second day of class (Wave 1); their perceptions of course value (intrinsic and utility) were measured several weeks into the semester, but before the first exam (Wave 2); and their interest in the course was measured during the last week of class (Wave 3). We also obtained students' final course grades from department records.

#### Participants and Setting

Participants were recruited from four sections of introductory psychology classes (approximately 350 students per section). Only students who were taking the course for graded credit were included in the sample. Classes were almost entirely lecture format. Students' grades were determined by their performance on several multiple-choice exams given throughout the semester. Final grades were assigned based on a normative curve recommended by the psychology department.

Wave 1 data collection was part of a departmental-wide survey (1,145 participants) for which students received extra credit in exchange for participation. Participants enrolled in our study at Time 2 (830 participants) when they completed consent forms and the accompanying survey during class time. Students were not compensated for their participation in the second and third waves. Some attrition did occur after enrollment in our study at Wave 2. First, 35 participants dropped the course before the end of the semester. Second, because data were collected during class time, students who were absent at Wave 3 ( $n = 132$ ) were not included in the study. Thus, the final sample used in data analysis included 663 students (215 men and 448 women) and represents 79.9% of the students who enrolled in our study at Wave 2. Additionally, 2 participants who received a grade of "incomplete" were not included in the course grade analysis.

#### Measures

**Initial measures.** During the second meeting of the course, after students had become familiar with the course syllabus and

materials, students completed a questionnaire that contained items assessing their initial interest in psychology, and their achievement goals for the semester. Initial interest in psychology was assessed with two items ("I think psychology is a very interesting subject," "I don't think psychology is a very interesting subject [reversed]";  $\alpha = .78$ ). Mastery-approach goals were assessed with two items ("My goal is to learn as much as possible about psychology," "I want to develop an understanding of psychology";  $\alpha = .80$ ). Performance-approach goals were assessed with two items ("I would like to do better than other students in this class," "My goal is to get a better grade than other students in this class";  $\alpha = .75$ ). The initial interest and achievement goal items were based on prior research (Harackiewicz, Barron, Tauer, & Elliot, 2002; Harackiewicz et al., 2008). Participants responded to all self-report items on a scale from 1 (*strongly disagree*) to 7 (*strongly agree*).

**Midsemester measures.** Four weeks into the course, and about 1 week prior to the first exam, students completed a questionnaire that contained items assessing their perceived values in the course and their interest in the course. Utility value was assessed with three items ("What I am learning in this class is relevant to my life," "The topics in this class are important for my career," "In general, material from this class is not useful to me [reversed]";  $\alpha = .72$ ). Intrinsic value was assessed with three items ("Lectures in this class are entertaining," "Lectures in this class drag on forever [reversed]," "I enjoy coming to lecture";  $\alpha = .82$ ). Interest in the course was assessed with the same two items used for the initial measure of interest ( $\alpha = .78$ ).

**Subsequent interest.** At the end of the semester, but prior to the final exam, students' final interest in the course was assessed. In addition to the items used to measure initial interest, the measure of subsequent interest included two behavioral inclination items ("I would like to take more psychology courses," "My experience in this course has made me want to take more psychology courses";  $\alpha = .87$ ).

**Final grade.** Students' final course grades were obtained from departmental records. Each student could receive one of seven possible grades, based on the university's 4-point scale. The average grade in this study was 2.92 ( $SD = 0.84$ ). Grades were distributed as follows: A = 21.5%, AB = 19.5%, B = 16%, BC = 17.4%, C = 20.7%, D = 4.7%, and F = 0.2%. Two students in our sample received an incomplete grade for the semester, but were retained in the interest analysis. The average grade for students in our sample was slightly higher than for all students in introductory psychology ( $M = 2.70$ ,  $SD = 0.97$ ,  $N = 1,267$ ), but the distribution of grades was similar.

### Results

#### Preliminary Analysis

**Attrition.** We conducted an analysis that compared the final sample ( $n = 663$ ) with those individuals who enrolled in our study at Time 2 but who were not included in the final sample because they either dropped the course or failed to attend class on the day of data collection ( $n = 167$ ). Comparisons were made on all the major variables in the study: initial interest, mastery-approach and performance-approach goals, intrinsic and utility value, subsequent interest, and final grade.

Independent-sample *t* tests revealed two significant differences. Effect sizes (Cohen's *d*) were computed for these differences,

revealing small to large effects. The final sample had higher scores on mastery-approach goals,  $t(825) = -2.57, p = .01, d = .24$ , and course grade,  $t(793) = -7.28, p < .01, d = .82$ .

*Descriptive and correlational analyses.* Means, standard deviations, correlations, and scale reliabilities for the variables in this study are presented in Table 1. Although the structure and content and grading distributions of the four classes were comparable, we tested for instructor differences on all variables. There were significant instructor effects on intrinsic value, utility value, and subsequent interest, indicating that students reported higher levels of intrinsic value, utility value, and subsequent interest with some instructors compared with others. Therefore, we included a set of three dummy-code terms to test and control for mean-level differences between the instructors in all subsequent analyses (Cohen, Cohen, West, & Aiken, 2003).

*Missing data.* It is possible that the attrition that occurred in this data set could be influencing the findings in a myriad of ways. A complete account of causality and interpretation issues due to missing data can be found elsewhere (Rubin, 1976). The number of people with available data is presented for each variable in Table 1. We created a dichotomous variable reflecting whether individuals had complete data across all study variables (coded 0) or had incomplete data on at least one variable (coded 1). This variable is included in Table 1. From the correlations between this variable and the other variables we can determine the extent to which incomplete data are related to other variables in the study. The bottom row of correlations shows that students with a lower final grade, lower initial interest, and lower mastery goals were more likely to have incomplete data. These associations indicate that the incomplete data are not missing completely at random, because if they were, then the missing pattern would not be related to any variables in the data set (Rubin, 1976). In addition, these associations enabled us to create a new data set that accounted for at least some of the variability in the missing data.

One approach to missing or incomplete data was to create imputed data sets that model what the data may have looked like if none of the data were missing. We used Mplus (Version 3.01), using full information maximum likelihood, to impute a complete data set that includes values on each variable for each individual

(Muthén & Muthén, 2006). The results of that analysis did not diverge from the analysis of only the originally complete data. Therefore, in this article, we report only the analyses using the original data set that did not account for missing data. A complete report of the maximum likelihood analysis is available from Chris S. Hulleman on request.

*Scale construction.* To test our hypothesis that the interest, utility value, and intrinsic value items would form separate factors, we conducted two types of factor analyses. First, in order to examine the factor loadings on our hypothesized three-factor model, we conducted an exploratory factor analysis of the items used to measure subsequent interest, utility value, and intrinsic value using a separate sample of undergraduates. As a part of a larger study on student attitudes toward learning, participants ( $N = 188$ ) were recruited from four sections of an introductory statistics course, and completed a brief survey during class time. The items and the pattern matrix of factor loadings are presented in Table 2. Each item loaded onto its respective factor (all values  $\geq .678$ ), and there was an absence of cross-loadings onto other factors (all cross-loadings  $< .300$ ).

Second, in order to test how well our model fit the data, we conducted a confirmatory factor analysis (CFA) using LISREL 8.72 (Jöreskog & Sörbom, 1998) on the current sample of introductory to psychology students ( $N = 663$ ). Five nested models were tested. The three-factor model—which separated interest, intrinsic value, and utility value—was tested against all other possible factor groupings: (a) a single factor that combined interest, intrinsic, and utility value items; (b) two factors: one interest factor and one combined intrinsic/utility value factor; (c) two factors: one utility value factor and one combined interest/intrinsic value factor; and (d) two factors: one intrinsic value factor and one combined interest/utility value factor. For each model, we calculated multiple indices of fit: chi-square, comparative fit index, standardized root-mean-square residual, and root-mean-square error of approximation. The results of the five confirmatory factor analyses are presented in Table 3. The hypothesized model—with distinct interest, utility, and intrinsic value factors—provided a better fit than any of the other models. The worst fitting model was the one that combined all three factors into one combined factor.

Table 1  
Means, Standard Deviations, and Correlations for Major Variables in Study 1

Variable	1	2	3	4	5	6	7	8
1. Initial interest	<i>0.78</i>							
2. Mastery-approach goals	0.62	<i>0.80</i>						
3. Performance-approach goals	0.09	0.21	<i>0.75</i>					
4. Utility value	0.36	0.38	0.07	<i>0.72</i>				
5. Intrinsic value	0.21	0.20	0.06	0.42	<i>0.82</i>

8. Missing data code	−0.08	−0.09	−0.01	−0.04	0.09	−0.24	−0.02	—
Minimum	1.00	1.00	1.00	1.00	1.00	1.00	1.00	0.00
Maximum	7.00	7.00	7.00	7.00	7.00	4.00	7.00	1.00
<i>M</i>	6.00	5.99	5.80	5.11	4.86	2.92	5.18	0.57
<i>SD</i>	1.10	1.02	1.25	1.04	1.14	0.84	1.25	0.49
<i>n</i>	1,150	1,145	1,145	830	830	661	663	1,150

Note. Correlations .08 and larger are significant at  $p < .01$ . Values along the main diagonal (in italics) are scale reliabilities. Missing data code: 0 = complete data, 1 = incomplete data. Dashes indicate that it was not possible to compute reliabilities.

Table 2  
Factor Analysis Pattern Matrix Factor Loadings from Statistics Sample (Study 1)

Variable	Factor		
	Interest	Utility	Intrinsic
Interest 1	.964		
Interest 2	.879		
Interest 3	.787		
Interest 4	-.678		
Utility 1		.843	
Utility 2		.728	
Utility 3		.696	
Utility 4		.689	
Intrinsic 1			.873
Intrinsic 2			.780
Intrinsic 3			-.699
Factor correlations			
Utility value	0.57		
Intrinsic value	0.59	0.42	

*Note.* Values are pattern matrix factor loadings from a factor analysis using principal-axis factoring with oblique rotation. Values less than .300 were omitted from this table. Interest 1 = "To be honest, I just don't find statistics interesting"; Interest 2 = "I think what we're learning in this class is fascinating"; Interest 3 = "I think the field of statistics is very interesting"; Interest 4 = "Statistics fascinates me"; Utility 1 = "I can apply what we are learning in Introductory Statistics to some of my other courses"; Utility 2 = "What I am learning in this class is relevant to my life"; Utility 3 = "I can apply what we are learning in Introductory Statistics to real life"; Utility 4 = "I think what we are studying in Introductory Statistics is useful for me to know"; Intrinsic 1 = "Lectures in this class are entertaining"; Intrinsic 2 = "I enjoy coming to lecture"; Intrinsic 3 = "Lectures in this class drag on forever."

### Regression Analyses

We used hierarchical multiple regression to analyze these data in three stages. First, we investigated the antecedents of achievement goals. Second, we examined the direct effects of task values, achievement goals, and initial interest on subsequent interest and course grade. Finally, we tested the indirect effects of all variables on subsequent interest and course grade. For all analyses, all continuous variables were standardized, and all two- and three-way interaction terms were computed (Aiken & West, 1991).

Significant interaction effects were interpreted in two ways. First, we computed predicted values for representative high and low groups (one standard deviation above and below the mean) from the regression equations using the unstandardized regression coefficients. Second, we calculated simple slope values for representative high and low groups from the regression equations and tested them according to Aiken and West (1991).

*Predictors of achievement goals.* The first set of analyses examined the antecedents of achievement goals. The achievement goal model contained the three instructor dummy codes, initial interest, and an effects code for gender (men = -1, women = +1). This five-term achievement goal model was used to predict both mastery- and performance-approach goals. Initial interest was the only significant predictor for both mastery-approach,  $t(662) = 19.69$ ,  $p < .01$  ( $\beta = .61$ ), and performance-approach,  $t(662) = 2.64$ ,  $p = .01$  ( $\beta = .11$ ) goals. Individuals with higher levels of initial interest reported higher levels of mastery- and performance-approach goals.

*Direct effects models.* The second set of analyses tested the direct effects of initial interest, mastery- and performance-approach goals, and all of their two- and three-way interactions on subsequent interest and final grade. We also included the gender effects code and the three instructor dummy codes. Preliminary testing indicated that none of the three-way interactions between initial interest, achievement goals, and gender attained significance on any measure, and they were dropped from all subsequent analyses. All two-way interactions were retained in the models. Therefore, the direct effects model contained 10 terms: the 7 main effect terms as well as 3 two-way interactions (Mastery-Approach  $\times$  Performance-Approach, Mastery-Approach  $\times$  Initial Interest, Performance-Approach  $\times$  Initial Interest).

*Direct effects on subsequent interest.* There was a significant main effect of initial interest,  $t(652) = 9.86$ ,  $p < .01$  ( $\beta = .46$ ), such that students who entered the course with higher levels of initial interest reported more interest in psychology at the end of the semester. The main effect of mastery-approach goals,  $t(652) = 3.60$ ,  $p < .01$  ( $\beta = .17$ ), indicated that students with higher levels of mastery goals at the beginning of the course were more interested in psychology. These two main effects were qualified by the significant interaction between mastery-approach goals and initial interest,  $t(652) = 5.35$ ,  $p < .01$  ( $\beta = .25$ ), which indicated that mastery-approach goals were a stronger predictor of subsequent

Table 3

Three factor	78.84** (17)		0.08	0.98	0.06

*Note.*  $N = 663$ . RMSEA = root-mean-square error approximation; CFI = comparative fit index; SRMR = standardized root-mean-square residual.

<sup>a</sup> Test of the difference in model fit with the three-factor model (separate interest, utility value, and intrinsic value factors).

\*\* $p < .01$ .

interest in psychology for those students with high levels of initial interest ( $\beta = .42$ ) than for those with low levels of initial interest ( $\beta = .01$ ). This interaction is graphed in the top panel of Figure 1.

**Direct effects on final grade.** There was a significant main effect of performance-approach goals,  $t(650) = 4.56, p < .01$  ( $\beta = .18$ ), such that students with higher levels of performance-approach goals obtained higher final course grades. The direct effects path model for final interest and final grade is presented in Figure 2. Although we tested for the effects of initial interest in all analyses, we did not include it in the path diagrams to enhance parsimony.

**Mediated (and indirect effects) models.** The third set of analyses tested the role of perceived task values as mediators or indirect paths between initial interest and goals and the final outcome measures. First, we tested whether achievement goals and initial interest were significantly related to task values by using the direct effects regression model to predict intrinsic and utility value. Second, we tested whether the mediators were related to the outcomes, while controlling for the original predictors, by including task values in the direct effects model. Therefore, we added intrinsic and utility value to the direct effects model, as well as all possible two- and three-way interactions between values, initial interest, and goals. For each set of analyses, only significant interactions were retained in the model. Thus, unless otherwise noted, the mediation model contained 12 terms: 10 terms from the direct effects model with the addition of the 2 value terms. Finally, to test the significance of mediated and indirect effects, we followed procedures outlined by Kenny, Kashy, and Bolger (1998) in which the indirect path is tested by creating a product term and dividing by its standard error. This technique has been shown to be robust to Type I errors (MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002).

**Direct effects on intrinsic value.** The significant main effects of initial interest,  $t(652) = 3.13, p < .01$  ( $\beta = .16$ ), and mastery-approach goals,  $t(652) = 2.53, p = .01$  ( $\beta = .13$ ), indicated that students with higher levels of initial interest and mastery-approach goals were more likely to find intrinsic value in the course topic. These main effects were qualified by their significant interaction,  $t(652) = 2.08, p = .038$  ( $\beta = .11$ ), which indicated that mastery-approach goals led to more intrinsic value for those students with high levels of initial interest ( $\beta = .24$ ), but not for those with low levels of initial interest ( $\beta = .02$ ). This interaction is presented in the middle panel of Figure 1.

**Direct effects on utility value.** The significant main effects of initial interest,  $t(652) = 6.32, p < .01$  ( $\beta = .30$ ), and mastery-approach goals,  $t(652) = 6.68, p < .01$  ( $\beta = .32$ ), indicated that students with higher levels of initial interest and mastery-approach goals were more likely to find utility value in the course topic. These main effects were qualified by their significant interaction,  $t(652) = 5.86, p < .01$  ( $\beta = .28$ ), which indicated that initial interest led to more utility value for those students with high levels of initial interest ( $\beta = .60$ ), but not for those with low levels of initial interest ( $\beta = .04$ ). This interaction is presented in the lower panel of Figure 1.

**Mediated and indirect effects on subsequent interest.** In the mediation model, the significant main effects of intrinsic value,  $t(650) = 3.84, p < .01$  ( $\beta = .14$ ), and utility value,  $t(650) = 6.33, p < .01$  ( $\beta = .25$ ), indicated that students who perceived each type of value in the course reported more interest in psychology at the

Figure 1. Interactive effects of mastery-approach goals and initial interest on subsequent interest and task values in Study 1. Interest = interest in psychology at the beginning of the semester; MAp = mastery-approach goals; PAp = performance-approach goals. The *Hi* and *Lo* prefixes indicate values at one standard deviation above and below the mean, respectively, for each variable. Each panel represents a significant two-way interaction between mastery-approach goals and initial interest. The top panel represents the interaction on subsequent interest, the middle panel represents the interaction on intrinsic value, and the bottom panel represents the interaction on utility value. The simple slopes for initial interest at one standard deviation above the mean of mastery-approach goals ( $\beta = .61, .28, .58$ ) and at one standard deviation below the mean of mastery-approach goals ( $\beta = .21, .05, .02$ ) were calculated for subsequent interest, intrinsic value, and utility value, respectively.

Figure 2. Study 1 path model of direct effects on course outcomes. <sup>a</sup>The significant mastery-approach direct effect on subsequent interest was qualified by its significant interaction with initial interest (see Figure 1 and the text). All paths are standardized regression coefficients from a simultaneous multiple regression that includes all direct effects in the model. All paths are significant at  $p < .01$ .

end of the semester. The main effect of initial interest was also significant,  $t(650) = 8.03$ ,  $p < .01$  ( $\beta = .36$ ), but reduced in size from the direct effects model ( $\beta = .46$ ). The formal test of mediation revealed that the effect of interest was partially mediated by both intrinsic value ( $z = 2.43$ ,  $p = .02$ ) and utility value ( $z = 4.47$ ,  $p < .01$ ). In addition, the mastery-approach goal main effect was no longer significant ( $\beta = .07$ ,  $p = .12$ ) and reduced in size from the direct effects model ( $\beta = .17$ ). The formal test of mediation revealed that the effect of mastery goals was partially mediated through both intrinsic ( $z = 2.11$ ,  $p = .03$ ) and utility value ( $z = 4.49$ ,  $p < .01$ ). The complete path model is presented in Figure 3. The interaction between initial interest and mastery goals remained significant in the mediated model,  $t(650) = 3.68$ ,  $p < .01$  ( $\beta = .17$ ), but reduced in size from the direct effects model ( $\beta = .25$ ). The formal test of mediation revealed that this interaction effect was partially mediated through both intrinsic value ( $z = 1.83$ ,  $p = .07$ ) and utility value ( $z = 4.30$ ,  $p < .01$ ).

**Mediated and indirect effects on final grade.** In the mediated model, the significant main effect of performance-approach goals was unchanged from the direct effects model,  $t(648) = 4.44$ ,  $p < .01$  ( $\beta = .18$ ). However, there was a significant main effect of utility value,  $t(648) = 3.94$ ,  $p < .01$  ( $\beta = .19$ ), such that students who perceived higher levels of utility value in psychology received

higher grades than students who perceived lower levels of utility value. Although initial interest and mastery-approach goals did not directly predict final grade, there were significant indirect paths from these variables to final grade through utility value ( $z = 3.34$ ,  $p < .01$ , and  $z = 3.39$ ,  $p < .01$ , respectively). The complete path model for final interest and final grade is presented in Figure 3.

### Structural Equation Model

In order to test the overall fit of the model, we used Lisrel 8.72 to simultaneously test the model presented in Figure 3. The results indicated that the overall model provided a satisfactory fit to the data,  $\chi^2(80, N = 663) = 309.44$ ,  $p < .001$ , root-mean-square error of approximation = .07, comparative fit index = .97, standardized root-mean-square residual = .07.

### Discussion—Study 1

The results of this study suggest that perceptions of task value play an important role in the development of subsequent interest, and are also associated with academic performance. Adopting mastery-approach goals was associated with the perception of utility and intrinsic value in the course, particularly for students already high in initial interest, and these task values were in turn associated with the development of subsequent interest. Perceptions of utility value were also positively associated with final grades. Taken together, these results highlight the important role of mastery goals in optimal motivation as they promote the perception of value.

This study replicated prior work on achievement goal effects in the college classroom and demonstrated that mastery-approach goals predicted subsequent interest in the course, whereas performance-approach goals predicted higher course grades (Harackiewicz, Barron, Pintrich, et al., 2002). In addition, this study extends prior research in several important ways. First, when we controlled for initial interest and achievement goals, utility and intrinsic task values were unique predictors of subsequent interest. In addition, the effects of both initial interest and mastery-approach goals on subsequent interest were mediated through the value students perceived in the course. Initial interest and mastery-

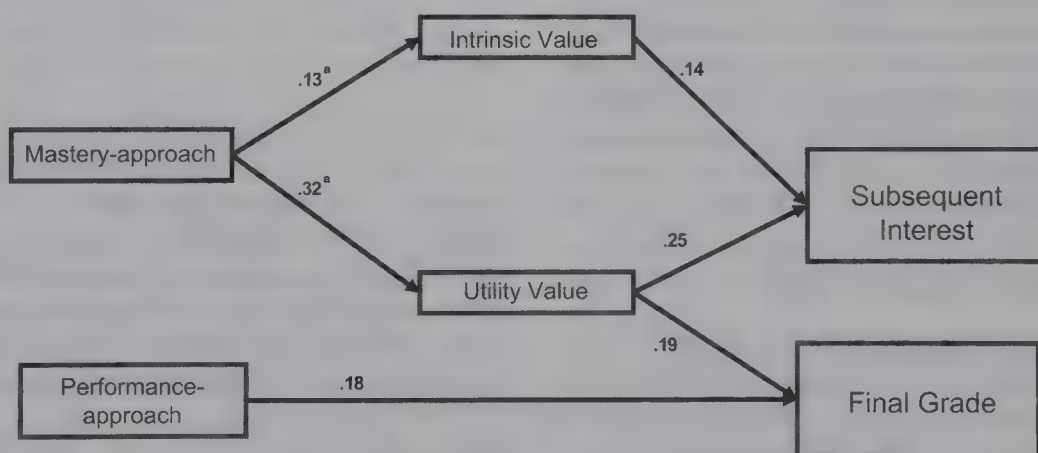

Figure 3. Study 1 path model of direct and mediated effects on course outcomes. <sup>a</sup>The direct effects of mastery-approach goals on intrinsic and utility value were moderated by significant interactions with initial interest (see text for details). All paths are standardized regression coefficients from simultaneous multiple regressions that included all the variables in the model. All paths are significant at  $p < .01$ .

approach goals predicted utility and intrinsic value in the course material, which predicted subsequent interest, supporting the four-phase model of interest development (Hidi & Renninger, 2006).

Second, perceiving utility value in the course was positively associated with higher course grades. This finding represents an indirect pathway through which initial interest and mastery-approach goals positively influenced academic performance. It is important to note that our results are not informative about the processes whereby task values were associated with subsequent interest and performance. Perhaps finding the material useful led students to make more meaningful connections between themselves and the material, which allowed them to learn the material more thoroughly, remember it better (Markus, 1977), and put more effort into the course (Mac Iver et al., 1991). Future research will need to explicate the mechanisms of the task value effects.

Third, the effects of mastery-approach goals on subsequent interest remained significant even when we controlled for initial interest. In fact, despite being highly correlated ( $r = .61, p < .01$ ), initial interest and mastery-approach goals had unique, independent effects on subsequent interest. In addition, the interaction between initial interest and mastery-approach goals revealed that mastery-approach goals were strongly predictive of subsequent interest only for students who were high in initial interest. In contrast, mastery-approach goals were unrelated to subsequent interest for individuals who entered the class with low levels of initial interest. Thus, the combination of initial interest and mastery-approach goals was particularly powerful in predicting task values and subsequent interest.

In Study 2, we sought to extend our analyses to a different achievement context, and we investigated task values and achievement goals at a sports camp. Participants were high school football players who participated in a summer football camp designed to prepare them for the upcoming season. In contrast to introductory psychology students in Study 1, the football players in Study 2 were more likely to have extensive experience playing football and thus entered the camp situation with more well-developed interest. This allowed us to investigate a proposition of Hidi and Renninger's (2006) model regarding the deepening of already well-developed individual interest. According to their model, well-developed individual interest is maintained and deepened through continued interaction with the activity: By re-engaging in the activity, individuals with well-developed interests can experience new-found situational interest—through knowledge and skill acquisition, finding new meaning and value, and experiencing positive affect—and thereby deepen their interest in the activity. In Study 2, we investigated the first step in this process by examining the development of situational interest in a domain in which individuals begin with a more well-developed individual interest.

### Study 2—Sports Camp

This study investigated the role of task values and achievement goals in predicting subsequent interest and performance at a summer football camp for high school boys, controlling for initial interest. High school sports camps provide opportunities for athletes to engage in their sport outside of the competitive season and to develop and extend their existing skills. These camps tend to attract individuals with high levels of experience and interest in the sport. Indeed, not only did our athletes report being interested in

football ( $M = 5.54, SD = 0.78$ ), but they also had been playing the sport for several years ( $M = 4.26, SD = 1.93$ ). Those campers who get the most out of camp are likely to leave camp with new skills as well as with a sense of enjoyment and satisfaction, having optimized their camp experience. Thus, our primary outcome measure in this study was camp satisfaction, reflecting situational interest in the camp experience.

This study extends prior achievement goal research by examining the influence of both types of approach achievement goals in the sports context. Prior research in sports contexts has assessed mastery-approach goals, but performance goals have typically been assessed as a combination of approach and avoidance motivation (Elliot, 2005) or within the ego-orientation perspective (Duda, 1995). On the basis of prior research in the classroom, we predicted that mastery-approach goals would predict satisfaction in a sports camp, whereas performance-approach goals would predict performance at camp. We also hypothesized that mastery goals would predict both intrinsic and utility task values. Consistent with the results of Study 1, we hypothesized that intrinsic value would predict camp satisfaction and that utility value would predict both camp satisfaction and performance.

In addition, because this research extends beyond the classroom, we can speculate about how achievement goal effects might differ in this particular sports context. Sporting contexts can differ from classrooms in that competition, rewards, and performance are inherent to the activity (Hidi, 2000; Kruglanski, 1975), and these components of the activity might enhance subsequent interest and intrinsic motivation (Hidi & Harackiewicz, 2000). Therefore, it is possible that performance-approach goals might positively predict camp satisfaction. However, it is also possible that mastery-approach goals might predict performance in this context. This is because football camp occurs outside of the regular competitive season and skill development could be more salient than normative performance at football camp, and more salient than in the classroom. Thus, this particular sporting context, in which skill development is an inherent part of the purpose of the activity, could provide the opportunity for achievement goals to work in ways that are different from the college classroom and reveal multiple pathways for optimal motivation (Barron & Harackiewicz, 2001; Hidi & Harackiewicz, 2000; Pintrich, 2000b).

## Method

### Overview

This study took place during a summer football camp for high school boys in the midwestern United States. Participants' initial interest in football and achievement goals were assessed on the first day of the camp (Wave 1), their task values for specific football drills were assessed during the middle of the camp (Wave 2), and their interest in camp was assessed at the conclusion of camp (Wave 3). Our dependent measure of performance consisted of coaches' ratings of campers' effort and performance at camp.

### Participants and Setting

Participants were recruited from two summer football camps for high school boys (approximately 200 campers per camp). Participants were entering 8th–12th grade in the coming fall (grade level

of participants: 8th = 0.8%, 9th = 14.3%, 10th = 24.4%, 11th = 26.9%, 12th = 33.6%). The football camps were either 3- or 4-day overnight camps that focused on teaching players football-relevant skills. Each day of camp included two or three practice sessions that were focused on skill development, allowing only minimal opportunity to scrimmage or play competitive games. Camp drills were divided into two categories: technique drills and competitive drills. Technique drills were defined as structured practice drills in which players were working individually on form or footwork, and not competing against someone. Examples of technique drills are form running, footwork drills, running routes, or pushing a blocking sled. Competitive drills were defined as structured practice drills in which players were competing against others, but not actually scrimmaging as an entire team. Examples of competitive drills are one-on-one passing and blocking drills.

Participants enrolled in our study when they completed the Wave 1 consent form and questionnaire on the first day of camp (237 participants). Players were not compensated for their participation in any of the surveys. Of the original 237 participants, 198 completed the Wave 2 measures, and 155 completed the Wave 3 measures. The participant attrition was primarily due to players needing to leave camp early because of schedule conflicts or participation in other summer sports events. Because the coach ratings were not dependent on participant attrition, the final sample for coach ratings was higher ( $n = 198$ , 84% of the original sample) than that for camp interest ( $n = 155$ , 65% of the original sample).

## Measures

*Initial interest and achievement goals.* Participants were mailed an initial questionnaire to complete and return when they checked into camp. This measure assessed participants' interest in football as well as mastery- and performance-approach goals for football camp. We adapted the initial interest measures for use in the football context from the final interest measures used in Harackiewicz, Barron, Tauer, and Elliot (2002), for example, "Football is my favorite sport to play." The specific items in this six-item scale had good reliability ( $\alpha = .78$ ) and can be found in the Appendix. Mastery-approach goal items focused on skill development at camp ("I want to develop my football skills at this camp," "I want to learn as much as possible at this camp," "I don't really care how much I learn at this camp [reversed]";  $\alpha = .72$ ). Performance-approach goal items focused on normative comparisons at camp ("It is important for me to do well compared to others at this camp," "My goal is to be one of the best football players at this camp," "I would like to do better than other players at this camp," "I don't care how I do compared to other players at this camp [reversed]";  $\alpha = .79$ ). The achievement goal items were adapted for the camp context based on Harackiewicz, Barron, Tauer, and Elliot (2002) and Conroy, Elliot, and Hofer (2003). All self-report measures in this study used a 7-point Likert scale that ranged from 1 (*strongly disagree*) to 7 (*strongly agree*).

*Utility and intrinsic value.* Approximately halfway through the camp participants completed a 10-item questionnaire that contained the task value measures. These value items were based on the model of values proposed by Eccles and Harold (1991) and assessed participants self-reported utility and intrinsic values of specific drills at camp. The six-item utility value scale focused on how useful the drills were in attaining other ends, ("Technique/

competition drills are useful for my football career," "Technique/competition drills are a good opportunity to improve and develop my football skills," "Technique/competition drills are valuable in developing football skills";  $\alpha = .92$ ). The four-item intrinsic value scale focused on how enjoyable campers perceived the drills to be ("Technique/competition drills are fun," "Technique/competition drills are my favorite part of camp";  $\alpha = .72$ ).

*Camp satisfaction.* At the conclusion of camp, participants' enjoyment and satisfaction with their camp experience was assessed with five items (e.g., "I had fun at camp," "Overall, I am satisfied with this camp";  $\alpha = .77$ ). The specific items are presented in the Appendix.

*Coach ratings.* Coaches' evaluations of each participant's effort and performance over the course of the camp were measured at the conclusion of camp. Coaches identified the campers with whom they worked most often. Each player was rated on how much effort each put forth during camp, and how well he performed compared with other campers, on a scale from 1 (*little effort/low performance*) to 9 (*high effort/performance*). The ratings for effort and performance were  $z$  scored within coach and combined to form an overall composite rating of performance and effort for each player ( $\alpha = .77$ ).

## Results

### Preliminary Analysis

*Attrition.* We conducted an analysis that compared the final sample ( $n = 155$ ) with those individuals who were not included in the sample because they did not complete Wave 2 or 3 ( $n = 82$ ). Comparisons were made on all the major variables in the study: initial interest, mastery-approach and performance-approach goals, intrinsic and utility value, camp satisfaction, and performance. Independent-sample  $t$  tests revealed no significant differences on any variables.

*Descriptive and correlational analyses.* Means, standard deviations, correlations, and scale reliabilities for the variables in Study 2 are presented in Table 4. Although the purpose and structure of the camps was similar, we tested for camp differences on all variables. Independent-sample  $t$  tests revealed that one camp was significantly higher in initial interest than the other camp,  $t(235) = 4.12$ ,  $p < .01$  ( $d = .52$ ). Therefore, we included a camp effects code ( $-1, 1$ ) to test and control for mean-level differences between the two camps in all subsequent analyses (Cohen et al., 2003).

*Missing data.* We addressed the issue of missing data in Study 2 as we did in Study 1. The results of analyses using missing data techniques that included all participants (regardless of whether their data were complete) did not diverge from those that only included participants with complete data. In this article, we report only the analyses using the original data set that did not account for missing data.

*Factor analyses.* We conducted a confirmatory factor analysis using Lisrel 8.72 in order to test whether the intrinsic and utility value items separated into distinct components. Since we did not measure interest at the same time as value, we only included the task value measures in this analysis. We tested two competing models. The one-factor model specified that all 10 items loaded onto one overall value factor. The two-factor model specified that there were two independent value constructs representing utility

and intrinsic value. As indicated in Table 5, neither model fit the data extremely well. However, the two factor model produced a significant better fitting model,  $\Delta\chi^2(1, N = 663) = 39.99, p < .01$ .

### Regression Models

We used hierarchical multiple regression to analyze these data. The primary analyses are divided into three parts. First, we investigated the antecedents of achievement goals. Second, we conducted a series of multiple regression analyses to examine the direct effects of initial interest, achievement goals, intrinsic value, and utility value on camp satisfaction and performance. Finally, we examined the indirect effects of all variables on camp satisfaction and performance. For all analyses, all continuous variables were standardized, and all two- and three-way interaction terms were computed (Aiken & West, 1991). Significant interactions were interpreted as in Study 1. Preliminary testing indicated that multicollinearity was an issue in this data set, in part because of the high degree of relationship between the value terms. For example, when all of the three-way interactions were entered simultaneously into the regression equation, tolerance values dropped to near zero for over half of the variables in the regression, which is an indicator of severe multicollinearity (Cohen et al., 2003). Therefore, when testing interactions, we were mindful of this problem and proceeded by testing the two-ways in one step, and the three-ways individually on a final step.

Table 5  
Confirmatory Factor Analysis Results from Study 2

Model	$\chi^2$ (df)	$\Delta\chi^2$ (df) <sup>a</sup>	RMSEA	CFI	SRMR
One factor	309.15** (35)	39.99** (1)	0.24	0.85	0.20
Two factor	269.16** (34)		0.23	0.87	0.18

Note.  $N = 155$ . RMSEA = root-mean-square error of approximation; CFI = comparative fit index; SRMR = standardized root-mean-square residual.

<sup>a</sup> Test of the difference in model fit with the two-factor model (separate utility and intrinsic value factors).

\*\*  $p < .01$ .

*Predictors of achievement goals.* The achievement goal model contained the camp effects code and initial interest. Initial interest was the only significant predictor for both mastery-approach,  $t(226) = 3.37, p = .001$  ( $\beta = .24$ ), and performance-approach,  $t(226) = 3.90, p < .01$  ( $\beta = .26$ ), goals. Individuals with higher levels of initial interest reported higher levels of mastery- and performance-approach goals, compared with those who had lower levels of initial interest.

*Direct effects models.* The second set of analyses tested the direct effects from initial interest, mastery- and performance-approach goals, and their two- and three-way interactions on camp satisfaction and performance. Nonsignificant interactions were trimmed from the final direct effects models. The camp effects code was also included.

*Direct effects on camp satisfaction.* There were significant main effects of initial interest,  $t(154) = 2.75, p < .01$  ( $\beta = .20$ ), and mastery-approach goals,  $t(154) = 3.10, p < .01$  ( $\beta = .22$ ). Players with higher levels of initial interest and mastery-approach goals reported more satisfaction with camp than those with lower levels of these variables.

In addition, there was a significant three-way interaction on camp satisfaction between initial interest, mastery-approach goals, and performance-approach goals,  $t(154) = -4.99, p < .01$  ( $\beta = -.38$ ). This interaction is graphed in Figure 4. Inspection of the predicted values indicated that players with low levels of initial interest reported the most camp satisfaction when both mastery and performance goals were high ( $\hat{Y} = 6.83$ ), compared with when both goals were low ( $\hat{Y} = 5.90$ ), when mastery goals were low and performance goals high ( $\hat{Y} = 5.93$ ), or when mastery goals were high and performance goals were low ( $\hat{Y} = 6.13$ ). In contrast, players with higher levels of initial interest demonstrated more camp satisfaction when only one goal type was high (high mastery/low performance,  $\hat{Y} = 6.83$ ; low mastery/high performance,  $\hat{Y} = 6.62$ ), and moderate levels of interest when both goals were high ( $\hat{Y} = 6.56$ ) or low ( $\hat{Y} = 6.43$ ).

*Direct effects on coach ratings.* There was a significant main effect of performance-approach goals,  $t(181) = 2.25, p = .03$  ( $\beta = .17$ ), such that players with higher levels of performance-approach goals received higher ratings of effort and performance from their

Figure 4. Interactive effects of initial interest, performance-approach, and mastery-approach goals on camp satisfaction in Study 2. The *Hi* and *Lo* prefixes indicate values at one standard deviation above and below the mean, respectively, for initial interest in football, mastery-approach goals (MAP), and performance-approach goals (PAp).

coaches. No other effects emerged. The direct effects path model for final interest and coach ratings is presented in Figure 5. Although we tested for the effects of initial interest in all analyses, we did not include it in the path diagrams to enhance parsimony.

**Mediated (and indirect effects) models.** The third set of analyses tested the role of perceived task values as mediators or indirect paths between initial interest and goals and the final outcome measures. First, we established that the predictors were significantly related to task values by using the direct effects regression model to predict intrinsic and utility value. Second, we established that the mediators were related to the outcomes, while controlling for the original predictors, by modifying the direct effects model to include task values. Therefore, we added intrinsic and utility value to the direct effects model, as well as all possible two- and three-way interactions between task values, initial interest, and goals. For each set of analyses, only significant interactions were retained in the model. Thus, unless otherwise noted, the mediation model contained 12 terms: 10 terms from the direct

effects model with the addition of the 2 value terms. Finally, we tested the significance of mediated and indirect effects as in Study 1 (Kenny et al., 1998).

**Direct effects on utility value.** The significant main effects of initial interest,  $t(193) = 3.39, p = .001$  ( $\beta = .25$ ), and mastery-approach goals,  $t(193) = 2.52, p = .01$  ( $\beta = .17$ ), indicated that students with higher levels of initial interest and mastery-approach goals were more likely to find utility value in the drills. No other effects were significant.

**Direct effects on intrinsic value.** The significant main effect of initial interest,  $t(192) = 5.01, p < .01$  ( $\beta = .35$ ), indicated that players with higher levels of initial interest were more likely to find intrinsic value in the drills. There was also a significant interaction between mastery- and performance-approach goals,  $t(192) = -3.46, p < .01$ , ( $\beta = -.23$ ). An inspection of the predicted values indicated that, for players with low levels of performance-approach goals, high levels of mastery-approach goals lead to more intrinsic value ( $\hat{Y} = 5.42$ ) than low levels of

Figure 5. Study 2 path model of direct effects on football camp outcomes. All paths are standardized regression coefficients from simultaneous multiple regressions that included only the direct effects in the model. All paths are significant at  $p < .05$ . \*The direct path from mastery-approach goals to camp satisfaction is moderated by a three-way interaction between initial interest, mastery-approach goals, and performance-approach goals (see the text for statistics).

mastery-approach goals ( $\hat{Y} = 4.75$ ). In contrast, for players with high levels of performance-approach goals, high levels of mastery-approach goals did not lead to more intrinsic value ( $\hat{Y} = 5.01$ ) than for players with low levels of mastery-approach goals ( $\hat{Y} = 5.21$ ).

*Mediated and indirect effects on camp satisfaction.* In the mediation model, the direct effect for utility value was significant,  $t(154) = 3.04, p < .01$  ( $\beta = .22$ ), indicating that players who perceived the drills to be useful reported more satisfaction with camp. The direct effect for intrinsic value was significant,  $t(154) = 2.03, p = .04$  ( $\beta = .16$ ), indicating that players who perceived the drills to be enjoyable reported more satisfaction with camp. The direct effect for mastery-approach goals was significant,  $t(154) = 3.05, p < .01$  ( $\beta = .19$ ), but reduced in size from the direct effects model ( $\beta = .22$ ). The direct effect of initial interest was no longer significant,  $t(154) = 1.32, p = .19$  ( $\beta = .10$ ), and reduced in size from the direct effects model ( $\beta = .20$ ). The formal tests of mediation indicated that the relationship between initial interest and camp satisfaction was fully mediated by utility value ( $z = 2.60, p < .01$ ) and intrinsic value ( $z = 1.88, p = .06$ ). The relationship between mastery-approach goals and camp satisfaction was partially mediated by utility value ( $z = 1.94, p = .05$ ). In addition to these main effects, the three-way interaction with initial interest, mastery-approach, and performance-approach goals remained significant in the mediated model,  $t(154) = -5.38, p < .01$  ( $\beta = -.39$ ).

*Mediated and indirect effects on coach ratings.* The significant main effect of performance-approach goals,  $t(178) = 2.26, p = .03$ , ( $\beta = .17$ ) indicated that players who adopted performance-approach goals performed better and put more effort into camp than those who did not adopt performance-approach goals. In addition, the interaction between initial interest and utility value trended toward significance,  $t(178) = 1.73, p = .09$  ( $\beta = .15$ ). This interaction is graphed in Figure 6. The simple slopes analysis indicated that utility value predicted coach ratings when initial interest in football was high ( $\beta = .24, p = .07$ ), but not when

initial interest was low ( $\beta = -.04, p = .62$ ). The complete path model for camp satisfaction and coach ratings is presented in Figure 7.

### Structural Equation Model

In order to test the overall fit of the model, we used Lisrel 8.72 to simultaneously test the model presented in Figure 7. The results indicate that the overall model provided a satisfactory fit to the data,  $\chi^2(27, N = 155) = 747.96, p < .001$ , root-mean-square error of approximation = .08, comparative fit index = .90, standardized root-mean-square residual = .14.

### Discussion—Study 2

Overall, the results of Study 2 are consistent with the results of Study 1 and with prior research. Both intrinsic and utility task values uniquely predicted satisfaction with camp, providing further evidence that these task values contribute to individuals' motivation. Campers who perceived football drills as enjoyable and useful for developing skills finished camp with greater overall satisfaction than did those who found less value in these drills. Mastery-approach goals and initial interest also predicted subsequent satisfaction with camp, and these effects were partially mediated by intrinsic and utility values. Thus, perceptions of value operated as a key process through which subsequent interest (i.e., camp satisfaction) was developed, replicating the findings of Study 1.

In addition, utility value, but not intrinsic value, predicted campers' performance at camp among those with high football interest. In other words, those who entered camp with a high level of interest in football and who perceived football drills as being instrumental for skill development were rated by their coaches as putting forth more effort and performing better. These effects are

Figure 6. Interactive effects of initial interest and utility value on coach ratings of performance in Study 2. Interest = initial interest in football before camp started; Utility = usefulness of camp drills. The *Hi* and *Lo* prefixes indicate values at one standard deviation above and below the mean, respectively, for initial interest in football and utility value.

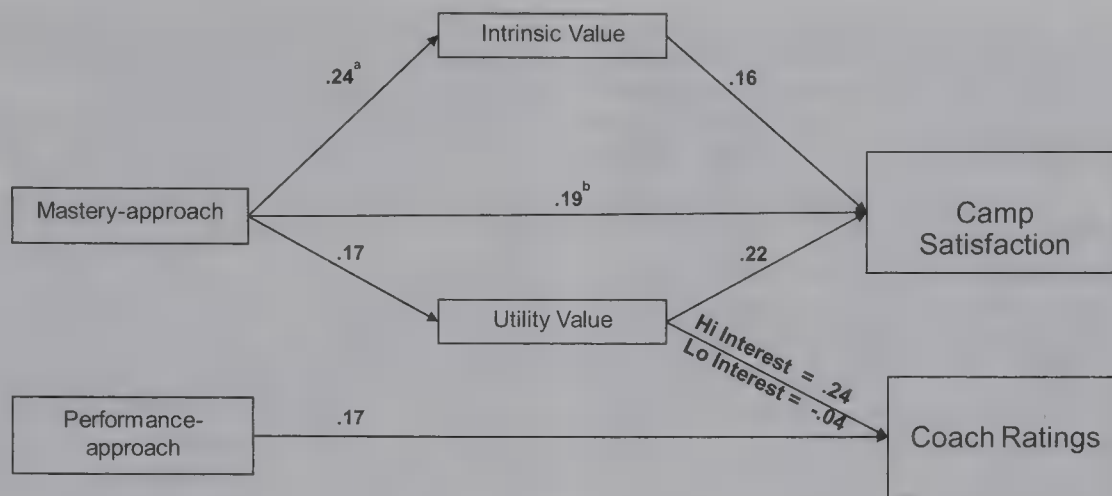

Figure 7. Study 2 path model of direct and mediated effects on football camp outcomes. All solid paths represent standardized regression coefficients from a simultaneous multiple regression that included all the variables in the model. All paths are significant at  $p < .05$  except the path from intrinsic value to camp interest ( $p = .06$ ), the path from initial interest to camp interest ( $p = .06$ ), and the interaction between initial interest and utility value on coach ratings ( $p = .085$ ). <sup>a</sup>The path from mastery-approach to intrinsic value is moderated by a significant interaction with performance-approach goals (see text for details). <sup>b</sup>The path from mastery-approach goals to camp satisfaction is moderated by a significant three-way interaction with initial interest and performance-approach goals (see the text for statistics).

comparable with the Study 1 finding that the perceived utility value of the course content predicted final grades.

The effects of achievement goals in this context were also comparable with the results of Study 1. The direct effects of mastery-approach goals on subsequent interest, and of performance-approach goals on performance, replicated the results of Study 1 as well as previous research (Harackiewicz, Barron, Pintrich, et al., 2002; Midgley et al., 2001), but within a sports context. This is important as there has been little work that assesses the effects of performance-approach goals on sports outcomes (e.g., Conroy et al., 2003; see Elliot, 2005, for a review). Moreover, as in Study 1, the effects of mastery-approach goals on subsequent interest were significant while we controlled for initial interest, suggesting that mastery goals play an important role in promoting subsequent interest in both contexts. Although initial interest and mastery goals were correlated,  $r(1150) = .61$  in Study 1, and  $r(237) = .20$  in Study 2, they each accounted for unique portions of the variance in subsequent interest. Thus, both studies provide strong support for the multiple goals perspective because both performance- and mastery-approach goals had positive effects on important outcomes.

One difference between the results obtained in the football camp and classroom studies was that mastery-approach goals did not predict intrinsic value in the sports context for everyone, whereas we did observe a main effect of mastery-approach goals on intrinsic value in the classroom. Rather, in the football camp, the effect of mastery-approach goals depended on the individual's level of performance-approach goals. Campers with high levels of either mastery- or performance-approach goals, but not both, perceived the most intrinsic value in camp drills. It is possible that pursuing one goal in the situation allowed the individual to find the enjoyable aspects of the drill, whereas pursuing both goals simultaneously prevented the individual from finding the enjoyable aspects of drills. In addition, the ratings of subsequent interest (i.e., camp satisfaction) were quite high in Study 2 ( $M = 6.33$  out of 7,

$SD = 0.75$ ) compared with Study 1 ( $M = 5.18$  out of 7,  $SD = 1.25$ ). Despite the potential for a ceiling effect in Study 2, achievement goals and task values were found to be significant predictors of subsequent interest, and these effects mirrored the pattern of findings found in Study 1.

Finally, Study 2 demonstrated the complexity of multiple goal effects (Barron & Harackiewicz, 2001, 2003). Not only did the effects of mastery goals depend on the level of performance goals, but these interactive goal effects also varied as a function of initial interest. For individuals with a lower initial interest in football, endorsing both goals was beneficial for subsequent interest. These individuals reported greater satisfaction with camp if they took advantage of the full range of achievement opportunities afforded them at camp, by focusing on both task mastery and performance relative to others. However, individuals who entered the camp situation with a higher initial interest in football benefited by adopting either a mastery-approach or performance-approach goal, but not both. One interpretation of this finding is that when individuals with elevated interest enter an achievement situation, it is motivationally adaptive for them to have one clear focus, or goal. These individuals are interested, paying attention, willing to engage in the task, and therefore need to focus on one particular objective. In contrast, when individuals with lower interest enter an achievement situation, it is motivationally adaptive to have multiple goals. These individuals are less interested and focused on the task, and therefore can benefit from many opportunities and objectives that can help them become task engaged. Put simply: Too many goals might frustrate and even distract the highly interested individual, whereas multiple goals might enable the less interested individual to remain engaged and motivated. It is unclear why this interaction appeared in Study 2 and not in Study 1. Future research will need to support this finding and its interpretations.

The relationship between performance-approach goals and subsequent interest found in Study 2 has not been found in classroom research (Harackiewicz, Barron, Pintrich, et al., 2002; Midgley et

al., 2001). The fact that we found such a relationship at a sports camp could be due to the enhanced salience of normative comparisons and competition. Performance-approach goals might predict subsequent interest in this context because competition and outperforming others is inherent to the game of football (Hidi & Harackiewicz, 2000; Kruglanski, 1975), and performance-approach goals are closely related to the object of the game. In the sports context, pursuing performance-approach goals may produce a more integrated type of self-regulation as comparisons with others are an inherent part of playing football (Deci & Ryan, 1985; Hidi & Harackiewicz, 2000). For example, a player has to be judged by the coaches to be better than other players at his position in order to play in the game. Consistent with this analysis, initial interest in football predicted both mastery-approach ( $\beta = .24$ ) and performance-approach goal adoption ( $\beta = .24$ ) to an equal degree. In contrast, the primary objective in college courses is to learn the material, and mastery-approach goals are most relevant to this objective. The results of Study 1 are consistent with this analysis as initial interest in the psychology class was a much stronger predictor of mastery-approach goals ( $\beta = .61$ ) than performance-approach goals ( $\beta = .11$ ). Considered together, the results of Studies 1 and 2 support the hypothesis that optimal motivation is a function of the match between an individual's adopted goals and the context (Harackiewicz, Barron, & Elliot, 1998; Harackiewicz & Sansone, 1991).

### General Discussion

The results of our research demonstrate the value of integrating multiple theoretical perspectives in the study of motivation. We demonstrated how achievement goals can operate as frameworks within which individuals perceive task value in activities, and how these task values may operate as proximal predictors of achievement outcomes. These conclusions are of course tempered by the correlational nature of our data; however, they do suggest potential pathways that can be further explored using causal methodology.

In addition, these results provide insight into the generalizability of motivational patterns across contexts. These classroom and sports camp contexts varied in terms of the type of activity (school vs. sports), participants' levels of prior experience with the activity (low vs. high), and age of participants (college vs. high school), respectively. In addition, we collected different measures of interest (course interest vs. camp satisfaction) and performance (course grades vs. coach ratings). Overall, there was remarkable consistency in the findings across the different measures in the two contexts. A comparison of the direct effects path models (Figures 2 and 5) and the mediated/indirect path models (Figures 3 and 7) reveals this similarity: Mastery-approach goals and initial interest both predicted subsequent interest, and these relationships were mediated by task values in both studies. Individuals in the classroom and on the playing field left the achievement situation with greater interest if they experienced intrinsic and utility value during task engagement. Moreover, performance-approach goals and utility value positively predicted performance in both studies, and the utility value effect revealed an indirect pathway from mastery-approach goals and initial interest to performance. Students and athletes both performed better when they found their respective tasks useful and personally meaningful. Adopting mastery-approach goals for the activity allowed students and ath-

letes to find intrinsic and utility value in the achievement tasks, and these values worked to promote both interest and performance in a classroom and on a football field.

Whereas little debate surrounds the association between intrinsic value and interest, some researchers have theorized that the relationship between utility value and interest is more complex (Eccles et al., 1983). Specifically, utility value has been described as sharing qualities with extrinsic motivation (Eccles & Wigfield, 2002), such that tasks that have high utility value are important not for the value inherent in doing them (Deci & Ryan, 1985), but for the value they have for engaging in other activities. Thus, the value is extrinsic to the immediate task, because it depends on its application to another situation (i.e., utility value is task extrinsic). Although many theorists have hypothesized that extrinsic motivators will impair the development of interest—whereas intrinsic, task-focused motivation will promote performance and interest (Ames, 1992; Deci & Ryan, 2000; Lepper & Henderlong, 2000)—the results of the current studies demonstrate that utility value is positively related to both motivation and performance. In addition, although task values and interest are correlated to a significant degree, the results of our confirmatory factor analyses demonstrate their empirical distinctiveness. This provides a foundation for continued research on the interrelationships of these unique—yet overlapping—constructs.

Some theorists have noted that utility value can be either intrinsic or extrinsic depending on why the task is perceived as useful (Malka & Covington, 2005; Simons, Vansteenkiste, Lens, & Lacante, 2004). For example, consider a football player who practices football drills during the off season in order to make the high school team. The immediate task (football drills) has utility value to the extent that it is instrumental in attaining a longer range goal (making the team). The utility of practicing football could be considered extrinsic if the player's parents (and not the player) want him to make the team (i.e., the goal is extrinsic). In contrast, the utility value could be considered intrinsic if the player has the personal goal of making the team (i.e., the goal is intrinsic). According to Simons, Vansteenkiste, Lens, and Lacante (2004), utility value can be intrinsic if its application is important to the person (i.e., person intrinsic) even if the value is not intrinsic to the task (i.e., task extrinsic). Research from this perspective has demonstrated that utility value, conceptualized as task extrinsic but person intrinsic, promotes motivation, interest, and performance compared with utility value that is person extrinsic (Simons, Dewitte, & Lens, 2000, 2003, 2004; Simons, Vansteenkiste, Lens, & Lacante, 2004; Vansteenkiste et al., 2004). Our measures of utility value emphasized the personal utility of the course content and football drills, and as such may be classified as person intrinsic. The positive relationship of utility value with important motivational outcomes in our studies provides support for the conceptualization of utility value as adaptive and beneficial (Brophy, 1999).

### *Implications for Multiple Goal Models, Limitations, and Future Research*

The generality of multiple goal effects on interest and performance was supported by our research. The pattern of achievement goal effects evidenced in previous classroom research was replicated in a sports context: Mastery-approach goals predicted inter-

est, and performance-approach goals predicted performance. In addition, these studies highlighted the intricacies of the multiple-goal perspective when considering optimal motivation (Barron & Harackiewicz, 2001, 2003; Harackiewicz, Barron, Pintrich, et al., 2002; Pintrich, 2003). In both the classroom and the football camp, mastery-approach goals were positively associated with subsequent interest when initial interest was high. However, when initial interest in football was low, mastery- and performance-approach goals worked synergistically to promote interest development. Clearly, more research is needed to further understand the relationship between multiple achievement goal adoption and interest.

In addition, now that there are more complete theoretical models of interest development (Hidi & Renninger, 2006), future research needs to test hypotheses about the contributions of task values and achievement goals in the development of interest. The current research provides insight into how these variables might work together, but further research is needed to continue to integrate these different motivational constructs and develop a more complete understanding of optimal motivation (Harackiewicz, Durik, & Barron, 2005; Pintrich, 2003).

The theoretical perspectives and constructs utilized in this research were extensions of our prior research integrating achievement goal and interest theory (Harackiewicz et al., 2000, 2008; Harackiewicz, Barron, Tauer, & Elliot, 2002; Harackiewicz et al., 2005; Hidi & Harackiewicz, 2000) and task value and interest theory (Durik, 2003; Durik & Harackiewicz, 2007; Godes, Hulleman, & Harackiewicz, 2007; Hulleman, Hendricks, & Harackiewicz, 2007). Our results are also consistent with other theoretical perspectives, such as the dual regulation systems proposed in the person-object-interaction model (e.g., Krapp, 2002, 2005), self-regulation research (Boekaerts, 2003), and models of volition (Kuhl, 2001). For example, in the person-object-interaction model (Krapp, 2005), the cognitive-emotional regulation system is responsible for developing connections between people and objects and activities, and this system has potential to add to researchers' understanding of situational interest. The cognitive subsystem, which is more reflective and conscious, could describe aspects of the perception of utility value, whereas the emotional subsystem, which is more reflexive and based on the person's immediate experience, could describe aspects of the perception of intrinsic value.

We acknowledge several limitations of this study. First, although we controlled for initial interest in the activities, we were not able to control for initial levels of performance in either of these studies. Controlling for initial levels of performance in our prior classroom research did not alter the effects of achievement goals on performance (Harackiewicz et al., 2000; Harackiewicz, Barron, Tauer, & Elliot; Harackiewicz et al., 2008), but without such controls in the present study, we do not know whether the effects of task value on performance would be impacted. Thus, future research needs to control for initial levels of performance, interest, and task values in order to make stronger claims regarding the causal influence of achievement goals and task values on educational outcomes (Maxwell & Cole, 2007). Second, our measure of subsequent interest in football camp reflected feelings of satisfaction as much as feelings of interest. Future research will need to replicate the interest findings in sports settings with measures that more closely parallel those used in the classroom.

Finally, although the research presented in this article highlights the important role that task values can play in the development of interest,

our results do not offer an explanation for how task values might facilitate the transition from situational interest to a more lasting form of personal interest. For example, if a student perceives utility value in psychology because it is instrumental in helping them gain admission into medical school, how does this task value lead to subsequent interest in psychology (rather than interest in medical school)? There are a number of possibilities that could be investigated. As interest researchers have suggested (e.g., Renninger, 2000), it is possible that finding meaning in psychology motivates students to spend more time studying and exploring psychology, which could then lead to a greater appreciation of the field and interest development. Additionally, students may become more engaged and involved with their learning, leading to feelings of task involvement and interest (Csikszentmihalyi, 1990; Dewey, 1913). These and other possible mechanisms responsible for the effects of task value on interest development warrant future exploration.

## Appendix

## Interest Items for Study 2

Scale	Items
Initial interest	1. Football is very important to me. 2. Football is my favorite sport to play. 3. During the summer I mostly prepare for football season. 4. I came to this camp because I thought it would be fun. 5. Football season is my favorite part of the year. 6. Football practice is my favorite part of the day.
Camp interest	1. I had fun at this camp. 2. Overall I am satisfied with this camp. 3. I am disappointed with this camp. 4. Instead of attending this camp, I wish I had worked out on my own. 5. Camp was a good use of my time.

Received April 16, 2007

# Striving for Social Dominance Over Peers: The Implications for Academic Adjustment During Early Adolescence

Sarah M. Kiefer  
University of South Florida

Allison M. Ryan  
University of Illinois, Urbana-Champaign

This study investigated the proposal that social dominance goals are an important, but overlooked, aspect of social goals for young adolescents' academic adjustment. Self-reports of social goals (dominance, intimacy, and popularity goals) early in the school year were used to predict subsequent engagement (self-reports and peer nominations of effort toward school work and disruptive behavior) and achievement (i.e., grades) when students were in 6th grade ( $N = 718$ ) and again after the transition to middle school when students were in 7th grade ( $N = 656$ ; 52% African American and 48% White; 52% female and 48% male). In line with hypotheses, social dominance goals were associated with maladaptive forms of engagement and low achievement in 6th and 7th grades. For intimacy goals, relations were more limited, but when found, these goals were associated with adaptive forms of engagement in 6th and 7th grades. Popularity goals were not generally associated with engagement or achievement. The exception was 6th-grade African American girls, for whom popularity goals were associated with maladaptive engagement (i.e., low effort, high disruptive behavior, and low peer nominations for trying hard and getting good grades).

**Keywords:** social goals, motivation, achievement, engagement, young adolescents

Students' goals are important to understanding their motivation, behavior, and achievement in school (Elliot & Dweck, 2005; Wigfield, Eccles, Schiefele, Rosser, & Davis-Kean, 2006). Goals are cognitive representations of things students want to accomplish and provide direction and energy for behavior (Ames, 1992; Elliot, 1999; Pintrich, 2000; Urdan, 1997). Academic goals, in particular achievement goals, have been the focus of much research and have provided insight into students' behaviors and performance in academic settings (Elliot & Dweck, 2005). However, students pursue a wide range of goals beyond academic achievement goals. Given the social nature of school, it is not surprising that students' social goals are increasingly being appreciated as important to understanding engagement and achievement in school (Anderman, 1999; Dowson & McInerney, 2001; Horst, Finney, & Barron, in press; Ryan, Kiefer, & Hopkins, 2004; Urdan & Maehr, 1995; Wentzel, 2005). The implications of social goals for engagement and achievement in school have received far less attention than academic goals and psychologists' understanding of the nature and consequences of social goals is far from complete. A social goal that has been largely overlooked is the goal for dominance among peers. No studies to date have examined the implications of social

dominance goals for academic adjustment. This is surprising given that strivings for dominance have held a prominent position in much research and theorizing on motivation and personality (McAdams, 1988; McClelland, 1985; Murray, 1938; Veroff, 1957; Winter, 1973). Further, recent research has highlighted that aggressive and manipulative behavior among students is prevalent and important to social adjustment in school (Cillessen & Rose, 2005; Hawley, Little, & Rodkin, 2007). Thus, the aim of the present study is to investigate the implications of social dominance goals for academic engagement (i.e., effort toward school work and disruptive classroom behavior) and achievement (i.e., grades).

## Different Approaches Used to Examine Links Between Social Goals and Academic Adjustment

A variety of approaches have been used to investigate students' social goals in relation to academic adjustment. First, researchers have asked students how often they try to do various things (e.g., have fun, follow rules) to describe their social goals with regard to what they are trying to accomplish with peers (often referred to as a *content approach* to goals; Ford, 1992; Wentzel, 2000). With this approach, Wentzel (e.g., 1992, 1996) established that social responsibility and prosocial goals positively relate to academic engagement and achievement. Building on Wentzel's work, Anderman (1999) documented that popularity goals negatively relate to academic engagement and achievement (see also Ryan, Hicks, & Midgley, 1997). Second, social goals have been conceptualized as distinct orientations toward social competence and have been linked to adjustment in the classroom (an *achievement goal approach* encompassing development and demonstration goals; Dweck & Leggett, 1988; Erdley, Cain, Loomis, Dumas-Hines, & Dweck, 1997; Ryan et al., 2004). A third approach has been to focus on a hybrid of social-academic goals (e.g., the goal to do

well academically to secure social approval or the goal to do well academically to fulfill a social obligation; Dowson & McInerney, 2001; Urdan & Maehr, 1995). These various approaches highlight different aspects of social goals and provide insight into connections between social goals and academic adjustment for students in schools. However, absent from all of these approaches is attention to social dominance goals.

### Social Dominance Goals as Representative of One of Three Basic Motives

In his seminal work, *Human Motivation*, McClelland (1985) identified three fundamental motivational systems that energize and direct behavior: power, achievement, and affiliation. The power motive concerns the desire to have impact, control, or influence over another person or group of people. The achievement motive concerns the desire to succeed with a consistent focus on doing things better. The affiliative motive encompasses the general desire to be with others as well as the desire for intimate relationships characterized by warmth and disclosure of personal thoughts and feelings. Other theorists have also drawn attention to the need for power as an important aspect of human motivation and have distinguished it from the need for affiliation in social relationships (McAdams, 1988; Murray, 1938; Winter, 1973; Winter & Stewart, 1978).

McClelland (1985) conceptualized the power, achievement, and affiliation motives as enduring traits and distinguished these broader motive systems from more specific goal strivings. We conceptualize goals as the concrete and situation-specific representations of the more abstract and general motivational dispositions (Elliot, 1999). As the more situation-specific manifestations of motive systems, goals should be related to situation-specific behaviors of students (i.e., engagement and achievement in school). Thus, we focus on the social dominance goals that students pursue in their peer relationships at school. We do not examine the antecedents of students' social dominance goals but assume they stem in part from individual differences in students' power motive as well as features of the social context (e.g., school culture, teacher behaviors, peer dynamics, parental values, and neighborhood setting).

We define social dominance goals as a focus on having power over peers, characterized by getting peers to comply with their wishes and instilling fear in peers. We acknowledge that this is not the only type of social goal that may emanate from the power motive. For example, a more positive manifestation could be a social goal focused on leadership. We investigate social dominance goals because recent research has suggested they are prevalent and important in the lives of young adolescents. Manipulative, indirect, and direct aggressive behavior has been found to play a central role in peer dynamics and social success (Cillessen & Rose, 2005). For decades, any type of aggressive behavior was considered a form of social incompetence and a correlate and precursor of peer rejection (operationalized as many *don't like* nominations and few *like* nominations from peers). However, recent research has highlighted that, when social status is measured with indicators such as *popular* or *cool* nominations instead of *like* nominations, manipulative, indirect, and even direct aggressive behaviors are often associated with high social status (Cillessen & Mayeux, 2004; Cillessen & Rose, 2005; Rodkin, Farmer, Pearl, &

Van Acker, 2000; Rose, Swenson, & Waller, 2004). It is important to note that social dominance goals are not synonymous with aggressive behavior. Aggressive behavior is one possible consequence of social dominance goals, or striving for power over peers. In our investigation, we examine the consequences of social dominance goals for engagement (effort and disruptive behavior) and achievement in school, and we hypothesize that there are serious costs of social dominance goals for these indicators of academic adjustment.

To fully understand the implications of social dominance goals, we examine them in tandem with two other social goals that represent McClelland's (1985) major motive systems: intimacy and popularity goals. Intimacy goals refer to a focus on establishing intimate peer relationships characterized by mutual support and disclosure of thoughts and feelings (Anderman, 1999; Jarvinen & Nicholls, 1996). Popularity goals refer to a focus on establishing high social status characterized by visibility and prestige within the larger peer group at school (Anderman, 1999; Jarvinen & Nicholls, 1996; Ryan et al., 1997). We view these two social goals as stemming, in part, from individual differences in students' affiliative and achievement motives. Here, too, we acknowledge that these are not the only two social goals that may emanate from these larger motives. Particularly for the achievement motive within the social domain, success and doing better in peer relations at school could take different forms. Students may try to improve their social skills and relationships relative to their own past experiences (i.e., a social development goal), or students may try to be better compared with others (i.e., a social demonstration-approach goal; see Dweck & Leggett, 1988; Ryan & Shim, 2006a, 2006b). Popularity goals are conceptually similar but more narrow in scope than social demonstration-approach goals. We chose intimacy and popularity goals because (a) they represent concerns that have been shown to be important in adolescent peer relationships (e.g., Bukowski & Hoza, 1989; Cillessen & Mayeux, 2004; Eder, 1985; Grotzinger & Crick, 1996; Hawley, 2003; Merten, 1997; Savin-Williams & Berndt, 1990) and (b) they have been associated with academic engagement (e.g., Anderman, 1999; Ryan et al., 1997). Given that we are proposing that social dominance goals are an important but overlooked aspect of young adolescents' social goals in school, it is important to demonstrate that the effects of social dominance goals exist above and beyond other social goals that have already been shown to predict engagement and achievement in this age group.

### Hypotheses for Social Dominance, Intimacy, and Popularity Goals and Academic Adjustment

Much theory and research indicate that social and academic adjustment are intimately related at school (e.g., Ladd, Kochenderfer, & Coleman, 1997; Patrick, 1997; Ryan, 2001; Wentzel, 2005). Social goals have implications for academic adjustment through the social behaviors as well as the types of social relationships they promote (Wentzel, 2005). Social dominance goals are likely to be associated with maladaptive forms of engagement and low achievement. A focus on having power over and instilling fear in peers is likely to lead to disruptive and off-task behavior and low achievement. In contrast, intimacy goals are likely to be associated with adaptive forms of engagement and achievement. A focus on building mutually supportive and close friendships is likely to lead

to positive behaviors, such as helping, cooperating, and sharing with peers. In line with this view, prosocial goals have been found to be positively associated with effort in the classroom (Wentzel, 1993), and intimacy goals have been found to be positively associated with positive attitudes toward school (Anderman, 1999).

Popularity goals are not expected to promote positive engagement and high achievement. Although much extant research has documented a positive association between social and academic success at school (see Rubin, Bukowski, & Parker, 2006, for a review), this association is generally found with measures that assess likeability among peers. When social status is measured as popularity, the association is much weaker (LaFontana & Cillessen, 2002). Students do not view effort and good grades in school as promoting popularity (Gorman, Kim, & Schimmelbusch, 2002; Juvonen & Murdock, 1993, 1995). The pursuit of popularity goals has been found to be related to negative attitudes about school (Anderman, 1999) and disengagement in the form of help avoidance (Ryan et al., 1997). Thus, we expect popularity goals to be associated with disengagement and low achievement. However, we expect that the associations for social dominance goals are stronger, because, given the content of social dominance goals as focused on being powerful, tough, and feared, the realization of such goals is likely to have a stronger association with disruptive and off-task behavior.

### Gender and Ethnicity

We examine gender and ethnic differences in social goals. In a recent review of research on gender differences in peer relationships, Rose and Rudolph (2006) concluded that boys tend to endorse more agentic and status-oriented goals, whereas girls tend to endorse more connection-oriented goals. These findings regarding social goals are in line with research showing that boys are socialized to be more competitive and dominant and girls are socialized to be more nurturing and caring (Eccles, 1993; Ruble, Martin, & Berenbaum, 2006). Thus, we expect boys to endorse social dominance and popularity goals more than girls do, and we expect girls to endorse intimacy goals more than boys do. Rose and Rudolph did not note any ethnic or racial differences in social goals, likely because most of the research has been on predominantly White samples. A contribution of the present research is that we address this gap. We hypothesize that ethnicity is associated with young adolescents' social goals, particularly social dominance goals.

McClelland (1985) theorized that a loss of or threat to one's power in society leads to a compensatory increase in the power motive. Thus, members of groups that are marginalized or discriminated against desire and focus more on exerting power than those who have not had such adverse social experiences. In support of this viewpoint, Veroff, Depner, Kulka, and Douvan (1980) found that African American men had higher power strivings than White men. Theory on the identity development of adolescent African American males in urban contexts describes a similar process. In response to discrimination and feelings of invisibility, African American males assume a *cool pose* (Cunningham & Meunier, 2004; Majors, 1991; Majors & Billson, 1992; Stevenson, 2004). The cool pose is a set of language and behaviors intended to display toughness, strength, and detachment. There is a bravado or macho attitude that encompasses the refusal to express emotions

that would render one vulnerable (Majors & Billson, 1992). In line with these ideas, we hypothesize that African American students (particularly males) are higher in social dominance goals and lower in intimacy goals compared with White students. We explore ethnic differences in popularity goals as well but generate no hypothesis, because these theories are more closely linked to social dominance and intimacy goals. In addition to group differences in mean levels, we also examine group differences in the nature of the relations of social goals to academic adjustment. This provides insight into whether the consequences of social goals for academic adjustment are the same for all groups and thus provides a more complete understanding (see Rowe, Vazsonyi, & Flannery, 1994, for a similar approach to understanding group differences in self-esteem).

### School Context

We conducted our study in the context of the transition to middle school in urban, predominantly low-income schools. The transition to middle school is a major event in the lives of early adolescents, which involves students adjusting to a larger and different school culture with many new students and different rules and norms of social and academic behaviors (Eccles, 2004). Transition stress may be exacerbated in low-income schools that have fewer resources to create emotionally supportive and high-quality instructional climates (Leventhal & Brooks-Gunn, 2000). Social relationships change dramatically because new friendships need to be formed and one's place in the social hierarchy must be redefined. Students go from being the oldest and the biggest students in elementary school to being the youngest and smallest in a new middle school. The salience and consequences of social dominance goals may change as students move from elementary to middle school. Pellegrini and Bartini (2001) found that being dominant was associated with aggression in new but not well-established social networks. Thus, the negative outcomes of social dominance goals, particularly for disruptive behavior, may be even stronger in the new setting of middle school.

### Overview of the Present Research

In summary, the present research examined the proposal that social dominance goals would have negative implications for students' academic adjustment at school. We conceptualize adjustment as both engagement (the behavioral involvement and participation necessary for school success) and achievement. To fully understand the role of social dominance goals for engagement and achievement, we consider social dominance goals in tandem with intimacy and popularity goals to identify whether there are unique effects. We expect that intimacy goals are positively associated with engagement and achievement. We expect that popularity goals are negatively associated with engagement and achievement (although less so than social dominance goals). Consistent with our conceptualization that goals precede academic adjustment, we used a prospective longitudinal design to examine whether social goals (dominance, intimacy, and popularity) measured in the fall of the school year predicted engagement (effort and disruptive behavior) and achievement (grades) measured in the spring (a 6-month time span). We used a variety of measures to assess engagement and achievement: self-reported effort, self-reported

disruptive behavior, peer nominations for working hard and getting good grades, peer nominations for not following school rules, and teacher-assigned grades. With a sample that was approximately half African American and half White, we examined gender, ethnic, and Gender  $\times$  Ethnic differences in the mean level of social goals as well as in the relations of social goals to engagement and achievement. We collected data from students when they were in their last year of elementary school (sixth grade) and again when they were in their first year of middle school (seventh grade) to examine whether the hypothesized relations between social dominance goals and engagement and achievement were stronger in the middle school context.

## Method

### *Schools*

The data were collected as part of the University of Illinois Adolescent Transitions Project, which is a 2-year longitudinal study examining changes in academic and social adjustment across the transition to middle school. Participants attended 1 of 15 elementary schools when they were in sixth grade and moved into 1 of 3 middle schools when they were in seventh grade. These elementary schools served nonmetropolitan, small urban communities. The average rate of eligibility for free or reduced-fee lunch across elementary schools was 66%, with 14 of the 15 elementary schools having greater than 50% of their students eligible and 1 school reporting 38% of their students as eligible. The average mobility rate (average number of students who transferred in or out of the school during the academic year) across elementary schools was 22%. The majority (12) had mobility rates between 20% and 29%, whereas 1 had a rate of 35%, and 2 had rates between 9% and 10%. The elementary schools had an average of 50% African American students, 46% White students, and 4% from other ethnic groups (13 of the 15 elementary schools had between 40% and 60% of both African American and White students, whereas 2 schools had slightly different configurations: 72%, 20%, and 8% and 57%, 30%, and 13% African American, White, and other ethnic groups, respectively).

At the middle school level, the average rate of eligibility for free or reduced-fee lunch across middle schools was 59% (45%, 55%, and 77% of students were eligible in each of the three middle schools). The average mobility rate across the middle schools was 24% (24%, 23%, and 23% for each of the three middle schools). The middle schools had an average of 48% African American students, 48% White students, and 4% from other ethnic groups (configurations were: 46%, 53%, and 1%; 37%, 61%, and 2%; and 59%, 31%, and 10% African American, White, and other ethnic groups, respectively, at each of the three middle schools).

### *Procedure*

Letters describing the project were given to all students to take home to their parents 2 weeks prior to each data collection. Given the substantial mobility rates in these schools, we maximized the sample size by recruiting new students at each wave. If parents did not want their children to participate in the study, they were instructed to have their child return an attached form to the teacher, call the school, or call the researchers at the university number

provided on the letter. All teachers were given two copies of the letter for each student, and teachers checked with students that the letters were delivered at home. Less than 5% of the parents declined to have their child participate at any wave.

Surveys were administered to students in their classrooms. Instructions and items were read aloud while students read along and responded. Students were told that the purpose of the survey was to find out about students' beliefs and behaviors. They were also told that the survey was not a test and that there were not right or wrong answers. Students were assured that the information in the survey would be kept confidential. In addition, they were told that filling out the survey was voluntary and that if at any point they wanted to stop, they could do so. We visited the schools 1 additional day to administer make-up surveys for students who were absent for survey administration.

### *Participants*

Given that the analyses examined the extent to which social goals in the fall predicted engagement and achievement in the spring, students who did not take the survey at both times within each year were dropped (20%). Further, students who were not African American or White were dropped because there were so few that it was not possible to analyze ethnic differences for these students. These restrictions yielded a sample of 718 students for Year 1 (52% female, 48% male; 52% African American, 48% White) and a sample of 656 students for Year 2 (53% female, 47% male; 52% African American, 48% White).

### *Attrition*

There were 373 students who were in both the first and second years of this study (i.e., completed surveys at all waves). Attrition was due to two factors: school participation and mobility rates. Regarding school participation, we lost some students who went to a nonparticipating middle school and gained some students from nonparticipating elementary schools (in total, three elementary schools and one middle school chose not to participate). After these students were accounted for, the sample instability was comparable with the mobility rates reported by the state for these schools.

We analyzed missing data to see if there were any significant differences between Year 1 students who remained in the study and those who were lost. There were no significant differences in social goals, self-reported effort, or self-reported disruptive behavior. However, students retained in the study had higher grade point averages, more peer nominations as students who try hard and get good grades, and fewer peer nominations as students who do not follow the rules compared with the students who were lost ( $t_s > 2.5$ ,  $p_s < .01$ ). Thus, in general, students who were retained had a more adaptive profile regarding academic engagement and achievement, which makes sense given that mobility is often due to financial strain and job instability within the family (Heinlein & Shinn, 2000). We also compared returning students with new students in Year 2 of the study but found no significant differences between these two groups.

### *Measures*

*Social goals.* Dominance, intimacy, and popularity goals were measured with items from the Social Goals Questionnaire (Jarvi-

nen & Nicholls, 1996). Given that the Social Goals Questionnaire was developed for and administered to high school students, we reviewed the items and chose the four items for each scale that were the most appropriate for sixth- and seventh-grade students. Social dominance goal items concern having power over peers. Intimacy goal items concern establishing intimate peer relationships. Popularity goal items concern establishing high social status. The items for each of the three social goal scales are displayed in Table 1. All items were rated on a 5-point scale (1 = *not at all true of me*, 3 = *somewhat true*, and 5 = *very true of me*). All items include the stem "I like it when," which focuses students on outcomes that would make them happy or feel successful. This is a unique feature to Nicholls's goal measures (e.g., Nicholls, Cheung, Lauer, & Pataschnick, 1989) compared with other measures of goals that use a range of stems such as "My goal is," "I try to," or "I want to" in addition to "I like it when" (e.g., Anderman, 1999). A study in the academic domain provided the validity information for this approach by documenting strong correlations ( $r > .63$ ) between analogous goal constructs with Nicholls's measure and another widely used measure, the Patterns of Adaptive Learning Survey (Midgley et al., 1998).

Because the items had not been administered to this age sample before, we conducted an exploratory factor analysis to ensure the social dominance, intimacy, and popularity goals were distinct constructs. Factor analysis is presented in the Results section and displayed in Table 1. Each of the three social goals was reliable in our sample in Year 1 (.83, .75, and .73 for dominance, popularity, and intimacy goals, respectively) and in Year 2 (.85, .76, and .79 for dominance, popularity, and intimacy goals, respectively). Social goals were fairly stable across the transition to middle school (fall of sixth grade to fall of seventh grade;  $r_s = .43, .46$ , and  $.45$  for dominance, intimacy, and popularity goals, respectively).

*Self-reports of classroom engagement.* Students reported on two facets of engagement in the classroom: effort and disruptive behavior. Items from the Rochester Assessment of Intellectual and Social Engagement were used to assess effort in school (see Miserandino, 1996; Skinner & Belmont, 1993). Sample items are

"I try very hard in school" and "I listen carefully in class." Students' disruptive behavior in class was assessed with a measure developed by Kaplan (e.g., Kaplan & Maehr, 1999). Sample items are "I disturb the lesson in class" and "I get into trouble in class." All items were rated on a 5-point scale (1 = *not at all true of me*, 3 = *somewhat true*, and 5 = *very true of me*). Each of the scales had four items, and all were found to be reliable in our sample at Year 1 ( $\alpha_s = .77$  and  $.74$  for effort and disruptive behavior, respectively) and at Year 2 ( $\alpha_s = .80$  and  $.80$  for effort and disruptive behavior, respectively). Engagement was fairly stable across the transition to middle school (spring of sixth grade to spring of seventh grade;  $r_s = .42$  and  $.53$  for effort and disruptive behavior, respectively).

The validity of the Rochester Assessment of Intellectual and Social Engagement has been demonstrated in research showing concordance between student and teacher reports of student effort (Skinner & Belmont, 1993). The validity of the disruptive behavior measure has been demonstrated in research showing that the more children reported their behavior as disruptive, the more official discipline referrals the children received (Kaplan & Maehr, 1999). In addition, children's reports of disruptive behavior, as assessed with this measure, are lower when teachers use effective management practices than when teachers do not do so (Patrick, Turner, Meyer, & Midgley, 2003).

*Peer nominations of classroom engagement.* We used Graham, Taylor, and Hudley's (1998) peer nomination measures in which students were asked, "Which students in your class work hard and get good grades?" and "Which students in your class do not follow school rules?" Students could nominate up to five same- or cross-gender peers in their grade for each question. Scores for peer nominations were calculated from the quotient of the number of nominations received by a student for a question over the number of classmates participating. A log transformation (with a small constant added to remove zero values) was applied to the peer scores to address the fact that peer nominations were not normally distributed, and then the peer scores were standardized by gender (see Rodkin et al., 2000). Peer nomination scores were fairly stable across the transition to middle

school (spring of sixth grade to spring of seventh grade;  $r_s = .32$  and  $.45$  for works hard and gets good grades and does not follow school rules, respectively).

**Achievement.** Students' spring semester grades in reading, math, science, English, and social studies were collected from their school records. The grades were coded F = 1 through A+ = 13. The overall spring semester grade point average was computed by taking the mean of the five subject grades. Grade point average was fairly stable across the transition to middle school (spring semester of sixth grade to spring semester of seventh grade,  $r = .67$ ).

Results

Exploratory Factor Analyses

A principal axis factor analysis with oblimin rotation was conducted on the 12 social goal items at Wave 1. Factors whose eigenvalues were greater than 1 were extracted. The analysis yielded three factors, which accounted for 61.91% of the total variance (see Table 1). The three factors corresponded to the three social goals: dominance, intimacy, and popularity goals. All factor loadings were above .55 on their primary factor. No items loaded on another factor at greater than .40. The factor analysis was run again with varimax rotation and similar results were found.

Preliminary Analyses of Means and Correlations

The means and standard deviations are shown in Table 2. The range for all three social goals was between 1 and 5 for both Years 1 and 2. Median values for social goals were as follows: dominance goals (Year 1 = 1.50, Year 2 = 1.50), popularity goals (Year 1 = 2.86, Year 2 = 2.71), and intimacy goals (Year 1 = 4.00, Year 2 = 3.75). To determine if there were statistically significant gender and ethnic differences in social goals, two-way analysis of variance procedures were conducted. As expected, there were gender differences in social goals. For both Years 1 and 2, boys endorsed social dominance goals more than did girls: for Year 1,  $F(1, 763) = 49.45, p < .001$ ; for Year 2,  $F(1, 758) = 90.52, p < .001$ . In addition, for both Years 1 and 2, boys endorsed popularity goals more than did girls: for Year 1,  $F(1, 759) = 15.83, p < .001$ ; for Year 2,  $F(1, 756) = 21.96, p < .001$ . Girls

endorsed intimacy goals more than did boys: for Year 1,  $F(1, 760) = 69.47, p < .001$ ; for Year 2,  $F(1, 757) = 69.71, p < .001$ . There were no Gender  $\times$  Ethnicity interactions, indicating that these gender differences were the same for both African American and White students. As expected, there were also ethnic differences in social goals. For Year 1, African American students endorsed social dominance goals and popularity goals more than did White students,  $F(1, 763) = 26.42, p < .001$ ;  $F(1, 759) = 4.63, p < .05$ , respectively. For Year 2, African American students endorsed social dominance goals more than did White students,  $F(1, 758) = 18.80, p < .001$ , whereas White students endorsed intimacy goals more than did African American students,  $F(1, 757) = 5.84, p < .05$ .

The correlations among variables for the entire sample are shown in Table 2. An expected pattern of correlations was found among the variables. For the most part, social dominance goals were associated with subsequent disengagement and underachievement in sixth grade and seventh grade. Popularity goals were also associated with subsequent disengagement and underachievement, but the pattern was weaker. In contrast, intimacy goals were positively associated with most measures of subsequent engagement and achievement. We do not present correlations broken down by gender and ethnicity, because we are most interested in unique effects of goals (i.e., controlling for other social goals, gender, and ethnicity). Thus, we examined whether the relation of social goals with engagement and achievement varied by gender and ethnicity in the multivariate regression models.

Multiple Regression Analyses Examining Social Goals, Engagement, and Achievement in Sixth Grade (Elementary School)

We conducted separate regression analyses for the five engagement and achievement variables in sixth grade (students' last year of elementary school; see Table 3). The social goals (measured in the fall) were entered with gender and ethnicity. Gender and ethnicity were dichotomous variables with 1 coded as female and African American, respectively. Preliminary analyses tested interactions among social goals, gender and ethnicity. For example, we tested Dominance Goal  $\times$  Gender, Dominance Goal  $\times$  Ethnicity,

and Dominance Goal  $\times$  Gender  $\times$  Ethnicity. We used procedures outlined by Aiken and West (1991) to test and interpret interactions. Main effect terms were standardized before computing interaction terms to avoid multicollinearity and aid interpretation of beta coefficients. Significance of interactions was determined if the  $R^2$  increased by a significant amount and if the beta coefficient for the interaction term was significant as well. Only significant interaction terms were retained in the final models (thus, the final models varied for different dependent variables). To interpret the significant interactions, we calculated the predicted values with unstandardized regression coefficients and conducted simple slope tests. Graphs were created with the predicted values of outcome variables for the students with goal scores one standard deviation above and below the mean.

**Social dominance goals.** As expected, social dominance goals were positively associated with subsequent disruptive behavior as well as peer nominations for not following the school rules. Further, social dominance goals were negatively associated with subsequent achievement. Thus, striving to be dominant and powerful among peers in the fall of the school year foreshadowed disruptive and disobedient behavior later in the year, according to both self-reports and peer nominations. Consistent with this pattern, a focus on dominance in peer relationships early in the school year was also associated with lower levels of achievement later in the school year. Social dominance goals were not associated with subsequent effort or peer nominations for effort/gets good grades.

There was a significant Social Dominance Goals  $\times$  Gender interaction for peer nominations of not following the rules, which indicated the positive association was stronger for girls compared with boys (see Figure 1). There was also a significant Social Dominance Goals  $\times$  Ethnicity interaction for peer nominations of not following the rules, which indicated a different relationship for White and African American students. Specifically, there was a positive association for social dominance goals and peer nominations of not following the rules for White students, but there was no association between social dominance goals and peer nominations for not following the rules for African American students (see Figure 2).

**Intimacy goals.** Intimacy goals were associated only with subsequent self-reports of effort. Thus, striving to have close relationships with friends in the fall was associated with increased levels of effort and involvement in tasks in the classroom in the spring. However, striving for an intimacy goal in the fall had no association with disruptive behavior, peer nominations, or grades.

**Popularity goals.** The relation of popularity goals to subsequent effort, disruptive behavior, and peer nominations of effort/gets good grades varied by gender and ethnicity. Specifically, there was a Popularity Goals  $\times$  Gender  $\times$  Ethnicity interaction indicating that the effects of popularity goals were different for African American girls compared with all other groups. Specifically, for African American girls, the endorsement of popularity goals in the fall was associated with lower subsequent effort, higher subsequent disruptive behavior, and fewer peer nominations of effort/gets good grades, whereas for all other groups, the relation of popularity goals to these outcomes was null (see Figures 3, 4, and 5).

One main effect was not qualified by any interaction: popularity goals were negatively associated with subsequent peer nominations of not following the rules. Thus, students who reported in the

Figure 1. Dominance Goal  $\times$  Gender interaction for peer nominations (PNs) of not following the rules (sixth grade).

Figure 2. Dominance Goal  $\times$  Ethnicity interaction for peer nominations (PNs) of not following the rules (sixth grade).

fall that they strived to achieve high social status were less likely to get nominations from peers as being students who did not follow the school rules.

#### Multiple Regression Analyses Examining Social Goals, Engagement, and Achievement in Seventh Grade (Middle School)

Next, we conducted separate regression analyses for the five engagement and achievement variables in seventh grade (students' first year in middle school; see Table 4) with the same model-building procedures as described for sixth grade.

**Social dominance goals.** The pattern we found for social dominance goals and academic adjustment in seventh grade was similar to that found for sixth grade. Social dominance goals were positively associated with subsequent disruptive behavior as well as peer nominations for not following the school rules. Additionally, in seventh grade, a negative association was found between social dominance goals and subsequent self-reports of effort. Thus, endorsement of social dominance goals in the beginning of middle school was associated with less positive forms of engagement (i.e., effort) and more negative

Figure 3. Popularity Goal  $\times$  Gender  $\times$  Ethnicity interaction for effort (sixth grade). Af. Am. = African American.

Figure 4. Popularity Goal  $\times$  Gender  $\times$  Ethnicity interaction for disruptive behavior (sixth grade). Af. Am. = African American.

forms of engagement (i.e., disruptive behavior and peer nominations of being a student who did not follow the rules) later in the school year. Similar to the findings in sixth grade, social dominance goals were not associated with peer nominations for effort/gets good grades in seventh grade.

In seventh grade, social dominance goals were negatively associated with subsequent achievement; however, a Social Dominance Goals  $\times$  Ethnicity interaction on achievement indicated that there was a negative association for social dominance goals and subsequent grades for White students, but there was no association for social dominance goals and grades for African American students (see Figure 6).

**Intimacy goals.** In the seventh grade, we found the same positive association between intimacy goals and subsequent effort that we found in the sixth grade. In addition, we found a positive association between intimacy goals and subsequent peer nominations of effort/good grades. Thus, striving to have close relationships with friends in the fall was associated with increased levels of self-reported and peer nominations for effort in the classroom in the spring.

**Popularity goals.** The three-way Popularity Goals  $\times$  Gender  $\times$  Ethnicity interactions that we found for several aspects of

Figure 5. Popularity Goal  $\times$  Gender  $\times$  Ethnicity interaction for peer nominations (PNs) of trying hard and getting good grades (sixth grade). Af. Am. = African American.

engagement in sixth grade were not found in seventh grade. In seventh grade, popularity goals were associated only with grades, and this association was qualified by a Popularity Goals  $\times$  Ethnicity interaction. The interaction indicated that the endorsement of popularity goals in the beginning of middle school was positively associated with subsequent grades for White students, but there was no association for African American students (see Figure 7).

### Discussion

The present research found support for the proposal that social dominance goals would have negative implications for students' engagement and achievement in school. In line with McClelland's (1985) conceptualization, factor analyses supported the assertion that social dominance goals are distinct from popularity and intimacy goals. Social dominance goals have not been the focus of recent research on students' social goals (see Anderman, 1999; Ojanen, Gronroos, & Salmivalli, 2005; Ryan & Shim, 2006a; Wentzel, 1996), but our findings indicate they are important in understanding the implications of social goals for academic adjustment during early adolescence. Dominant and aggressive be-

haviors are prevalent and important to social status in school (see Cillessen & Rose, 2005, for a review). Although there may be some benefits for dominance strivings in terms of social adjustment (as established in previous research, see Hawley et al., 2007), findings of the present study establish that there are serious costs regarding academic adjustment.

In both sixth and seventh grades (students' last year of elementary and first year of middle school), student endorsements of social dominance goals in the fall were associated with maladaptive forms of engagement and lower achievement in the spring. Although effects were not significant for every indicator of engagement, results did encompass both self-reported and peer nominated measures of engagement. When students are focused on establishing power over their peers (making others do what they want and establishing their toughness), they are more likely to act in ways that disrupt classes and are less likely to put effort into their school work. Not surprisingly, social dominance goals were associated with lower achievement. This pattern is not surprising as establishing power over others is inconsistent with the social responsibility, cooperation, and general good citizenship that teachers encourage and expect in the classroom.

*Figure 6.* Dominance Goal  $\times$  Ethnicity interaction for grade point average (G.P.A.; seventh grade).

*Figure 7.* Popularity Goal  $\times$  Ethnicity interaction for grade point average (G.P.A.; seventh grade).

The findings regarding ethnic and gender differences in the level of social goals were in line with McClelland's (1985) theorizing about need for power and Majors's (1991) theorizing about identity development. McClelland theorized that a group's loss of power in society leads to a compensatory increase in the power motive, and Majors theorized that African American males assume a cool pose of toughness, bravado, and emotional detachment in response to discrimination. Congruent with the ideas of both of these scholars, when compared with White students, African American students were higher on social dominance goals in both sixth and seventh grades and lower on intimacy goals in seventh grade. Additionally, being male was associated with increased social dominance and decreased intimacy goals in both sixth and seventh grades. Thus, ethnicity and gender both contributed to increases in social dominance goals. This pattern is consistent with research documenting that these groups are more at risk for disengagement and underachievement in school (Graham & Hudley, 2005). For males, striving for social dominance among peers may be a way of achieving society's ideal masculine traits (e.g., independent, assertive, and powerful; Pleck, Sonenstein, & Ku, 1993). For African American students, striving for social dominance among peers may also be a way to assert oneself and gain control in the school setting in reaction to discrimination (see Simons et al., 2002). Our findings dovetail with research showing that perceptions of discrimination are associated with academic disengagement and disruptive behavior at school (Taylor, Casten, Flickinger, Roberts, & Fulmore, 1994). Collectively, our findings suggest that social dominance goals may be an important aspect of motivation relevant to understanding masculinity, ethnicity, and engagement in school.

There were group differences in the mean levels of social goals, but the pattern of effects for social dominance goals was quite similar across gender and ethnicity. An Ethnicity  $\times$  Social Dominance Goals interaction in sixth grade indicated that, although social dominance goals were positively associated with peer nominations of not following rules for White students, there was no association for African American students. An Ethnicity  $\times$  Social Dominance Goals interaction found in seventh grade indicated that, although social dominance goals were negatively associated with achievement for White students, there was no association for African American students. Thus, there was some suggestion that the maladaptive effects of social dominance goals may not have been quite as pervasive for African American students as for White students. Although social dominance goals may be a negative factor, other issues may be more important to understanding African American students' engagement and achievement. However, even for African American students, the pattern revealed that social dominance goals were maladaptive (e.g., two out of three indicators in sixth grade and three out of four indicators in seventh grade). Further, endorsement of social dominance goals did not promote engagement and achievement in school for any students in either year.

The findings were more limited, but quite consistent, regarding intimacy goals. In both sixth and seventh grades, endorsement of intimacy goals was positively associated with subsequent self-reports of effort. In seventh grade, endorsement of intimacy goals was associated also with peer nominations of effort/good grades. Thus, consistent with prior research, striving for intimacy with peers seems a positive orientation toward peer relations that also

facilitates positive behavior in the classroom (Anderman, 1999; Wentzel, 1993). The desire to make peers happy, understand their feelings, and help them when they need it is consistent with the values teachers would promote among peers in the classroom. The pattern of effects for intimacy goals was identical across gender and ethnicity in both elementary and middle school years.

For the most part, popularity goals were not associated with engagement and achievement in sixth or seventh grade. This pattern, in combination with the limited findings for intimacy goals, supported our proposal that social dominance goals are an important but overlooked aspect of social goals, because social dominance goals were the strongest predictor of academic adjustment. However, there was an exception in the effects of popularity goals for African American girls. For African American girls in sixth grade, popularity goals were associated with maladaptive engagement (i.e., low effort, high disruptive behavior, and low peer nominations as a student who tries hard and gets good grades). Thus, the endorsement of popularity goals (wanting to be popular and get everyone to like them the best) seems to have a different meaning and implications for African American girls. African American girls may pursue and maintain popularity in a way that is distinct from that of other students. Cultural differences in the female role between African American and White students may partially explain how and why strivings for social status play out so differently for African American girls in the school setting. Scholars have noted that there is an emphasis on being strong and outspoken (in addition to caring and nurturing) for girls in African American compared with European American cultures (Basow & Rubin, 1999; Binion, 1990). African American girls who are popular (or trying to be popular) may have a strong vocal presence that does not conform to teachers' expectations of a good girl (i.e., quiet and obedient) in the classroom. Thus, teachers may respond differently to popular girls depending on their ethnicity (see Wright, 2005, for a qualitative study documenting such dynamics). It is interesting that in middle school, this pattern of academic maladjustment ensuing from popularity goals was not found. Instead, popularity goals were associated with higher grades for White students but were not associated with grades for African American students. Further investigation of the nature and meaning of popularity for boys and girls from diverse ethnic groups with attention to academics and teacher perceptions and behaviors could shed some light on how social and academic issues may intersect differently depending on ethnicity and gender.

Future research that uses additional methodologies could be informative. For example, student reports about social goals could be considered with observational data of regular classroom activities or specific tasks assigned to students with peers to provide insight regarding how social goals relate to what students say or do in the classroom or in social tasks. Such research could complement the broader patterns documented in the present study with a richer description of discourse and specific behaviors for both students and teachers.

Another important direction for future research is to investigate school and classroom factors that may minimize the pursuit of social dominance goals or ameliorate their impact on engagement and achievement. If the power motive is a basic human motive, can teachers help channel this motive toward more positive types of social goals, such as leadership? McClelland (1985) believed individuals' motives could be shaped and altered not only to improve

individual outcomes but to better society at large. Examinations of how the school and peer group contexts foster social dominance goals could provide insight about how to structure settings to better support students' learning and achievement.

Although the present findings raise many questions and interesting avenues for future research, the pattern of results regarding social dominance goals and academic adjustment is quite clear. In both sixth and seventh grades, for all students, pursuit of social dominance was associated with maladaptive forms of engagement and lower achievement. These findings contribute to theory on social motivation by highlighting a social goal that has received little attention to date. Further, these findings broaden the understanding of the factors that contribute to engagement and achievement in school with attention to gender and ethnicity. In conclusion, the present research highlights that attention to both social and academic competencies of students, as well as how they intersect, is important for a full appreciation of young adolescents' success in school.

# Do Peers Contribute to the Likelihood of Secondary School Graduation Among Disadvantaged Boys?

Marie-Hélène Véronneau, Frank Vitaro, Sara Pedersen, and Richard E. Tremblay  
Université de Montréal

This 17-year longitudinal study tested whether low peer-perceived acceptance and association with aggressive-disruptive friends during preadolescence predicted students' failure to graduate from secondary school. Participants were 997 Caucasian, French-speaking boys from low-socioeconomic status, urban neighborhoods. The boys were recruited in kindergarten (age 6) and followed through early adulthood (age 23). Low levels of prosocial behaviors and high levels of aggressive-disruptive behaviors in childhood were expected to predict negative preadolescent peer experiences. Adolescent academic achievement and school commitment were expected to mediate the link between preadolescent peer experiences and early adulthood graduation status. Results of structural equation modeling analyses tended to support these hypotheses. Greater childhood aggression-disruptiveness positively predicted friends' preadolescent aggression-disruptiveness. Having aggressive-disruptive friends, in turn, was related to a lower likelihood of graduation. Lower academic achievement and school commitment partially mediated the association between friend characteristics and graduation. Peer acceptance did not contribute to graduation.

**Keywords:** friendship, peer acceptance, academic adjustment, school graduation, longitudinal studies

Failure to graduate from secondary school has been related to problems at both individual and societal levels. At the individual level, such psychosocial problems as difficulties finding and maintaining employment, loss of wages, psychological maladjustment, and lower rates of community involvement have been associated with low educational attainment (Kaplan, Damphousse, & Kaplan, 1994; Kerckhoff & Bell, 1998; McCaul, Donaldson, Coladarsi, & Davis, 1992). At the societal level, major social and economic changes, such as the aging of the workforce, technological innovations, and market globalization (Organisation for Economic Co-Operation and Development, 2005) have put increased pressure on industrialized countries to maintain a well-trained workforce. A high rate of secondary school graduation is one important goal societies must achieve in order to meet this global educational challenge.

Research that enhances our understanding of the experiences that might influence students' abilities to earn secondary school

diplomas is an essential first step toward increasing the secondary school graduation rate. The role of familial and individual factors in the process leading to secondary school graduation was extensively investigated during the second half of the 20th century (see reviews by Ekstrom, Goertz, Pollack, & Rock, 1986, and Rumberger, 1987). In contrast, studies assessing the contribution of peers to secondary school graduation are still scarce, despite the important role that peers play in adolescents' lives (Hymel, Comfort, Schonert-Reichl, & McDougall, 1996; Vitaro, Larocque, Janosz, & Tremblay, 2001). The current study focuses on peer-related variables as potentially important contributors to individual graduation outcomes in boys. Boys graduate from secondary school at much lower rates than girls, and thus are of particular concern (Bowlby & McMullen, 2005).

## Preliminary Conceptual Clarifications

As put forward by Christenson, Sinclair, Lehr, and Godber (2001), graduation (or the failure thereof) from school should be distinguished from school persistence and its opposite, school interruption (i.e., school dropout). Graduation refers to the completion of the school program as attested to by a diploma, whereas school dropout refers to an interruption of school attendance, which may be definitive (i.e., permanent dropout) or followed by a return to school (i.e., temporary dropout). Christenson and her colleagues found this distinction useful for designing interventions aimed at enhancing students' academic attainment; we suggest that this distinction is also crucial in the context of nonexperimental, descriptive research. In fact, Entwisle, Alexander, and Olson (2004) found that temporary dropouts who eventually graduate usually become well-adjusted adults, whereas permanent dropouts (i.e., those who do not graduate) often suffer psychosocial problems. In other words, it is not the interruption of school attendance

per se, but rather the failure to complete the full academic program that most likely affects adjustment.

Nevertheless, because few studies use graduation as an outcome, it is useful to rely on dropout research to help identify relevant risk factors for the failure to graduate. In a review of the dropout literature, Rumberger (1987) made a distinction between structural risk factors for dropout (e.g., socioeconomic status [SES] and gender) and manipulable variables that are likely to explain the process of school disengagement (e.g., students' behaviors or some aspects of the social milieu). Although Rumberger acknowledged the predictive value of the structural risk factors, he suggested that future research should focus on manipulable variables because these can be targeted by interventions aimed at increasing graduation rates. This is why we focused on potentially manipulable social processes involving peers.

### An Integrative Theoretical Model of Secondary School Graduation

The current research was guided by an integrative model of secondary school graduation. This global model includes different types of predictors and processes that have been proposed by two complementary theoretical perspectives, namely, the social interactional perspective and the participation-identification perspective of school withdrawal.

#### *Sociofamilial, Behavioral, and Peer-Related Antecedents of the Failure to Graduate: Contributions of the Social Interactional Perspective*

The social interactional perspective was introduced by Patterson and his colleagues to study the pathways toward antisocial behavior, a broad concept that includes school dropout as well as many other socially deviant behaviors (Patterson, DeBaryshe, & Ramsey, 1989; Patterson, Forgatch, Yoerger, & Stoolmiller, 1998; Patterson, Reid, & Dishion, 1992). From this perspective, the failure to graduate is the end result of a developmental pathway that starts at home, where young boys develop a coercive behavior pattern. Such behavior then leads to rejection by normative in-school peers and to the affiliation with deviant peers who reinforce problem behaviors and attitudes that are incompatible with academic success.

More precisely, according to this view, the family context in the preschool years—especially inefficient, harsh, and inconsistent parenting practices—often paves the way for antisocial behavior. Consistent with Rumberger's (1987) review of risk factors for school dropout, children born to families of lower SES are particularly likely to be raised in a risky family climate. The high stress levels experienced by parents living in precarious financial conditions in combination with their typically lower educational attainment may heighten the likelihood that they will use coercive and inconsistent parenting practices. In addition, low-SES parents are less likely to adopt the beliefs and behaviors that contribute positively to their children's academic success (Davis-Kean, 2005).

When a child raised in a risky family context enters school, the coercive pattern of behavior he or she has developed in response to the family environment may interfere with adaptation to the new milieu, because such behaviors are in contradiction to the prevailing social norms for effective interpersonal interactions outside of

the family environment. Among other aspects of the child's psychosocial adjustment, experiences with peers may be severely affected by this lack of social skills. In the context of the social interactional perspective, two types of peer experiences have been examined, often separately.

First, peer acceptance or rejection by the peer group is thought to be crucial to children's psychosocial development. In Sullivan's (1953) interpersonal theory, peers act as socializing agents, rewarding acceptable behaviors in other children through positive interactions. These positive interactions lead to the successful fulfillment of the child's need for group belongingness. Conversely, peers discourage unacceptable conduct by avoiding interactions with—or rejecting—children who display aggressive, disruptive, or coercive behaviors. Empirically, several studies have established that children displaying high levels of aggressive behavior and low levels of prosocial behavior are at greater risk of being rejected by their peers (Coie, Dodge, & Kupersmidt, 1990; Ladd & Troop-Gordon, 2003; Taylor, 1989; Vitaro, Tremblay, Gagnon, & Boivin, 1992; Wentzel, 2003). In turn, low levels of prosocial behaviors, high levels of aggressive behavior, and peer rejection are related to a heightened risk of school dropout (Ollendick, Weist, Borden, & Greene, 1992; Vitaro, Brendgen, Larose, & Tremblay, 2005).

Second, in addition to peer rejection, friends' deviancy also represents a fundamental aspect of the peer experience that is related to school dropout in boys (Vitaro et al., 2001). According to the social interactional perspective, forming friendships with deviant peers is an important step in the pathway toward antisocial behavior and, in the context of the current study, toward the failure to graduate from secondary school. Patterson et al. (1992) theorized that youngsters who are rejected by the peer group affiliate with other aggressive, rejected children in order to fulfill their socioaffective needs, and empirical studies have supported this idea (Brendgen, Vitaro, & Bukowski, 1998; Dishion, Patterson, Stoolmiller, & Skinner, 1991; Laird, Jordan, Dodge, Pettit, & Bates, 2001; Vitaro, Pedersen, & Brendgen, 2007). However, friendships among aggressive and rejected students are usually short-lived and low in quality (Bagwell & Coie, 2004; Dishion, Andrews, & Crosby, 1995; Parker & Asher, 1993). As a result, these unsatisfying friendships may have a negative rather than a positive impact on psychosocial and academic outcomes in children and adolescents (Burk & Laursen, 2005; Ladd, Kochenderfer, & Coleman, 1996; Lansford, Criss, Pettit, Dodge, & Bates, 2003).

This may be especially true if friends of future school dropouts have similarly negative school-related experiences, including academic failure and rejection by peers and school staff, as well as feelings of alienation from school (Ekstrom et al., 1986). Through the process of peer socialization (Kandel, 1978), deviant friends may reinforce or model attitudes and behaviors that are incompatible with school success (Dishion, McCord, & Poulin, 1999). There is preliminary support for the hypothesis that students who associate with friends who reject school are more likely to disengage from school (Battin-Pearson et al., 2000; Pittman, 1991). Such disengagement can lead to truancy and school dropout.

The main strength of the social interactional perspective is its explicit acknowledgment that several types of risk factors work together from the earliest years of life to deter some individuals from following adaptive psychosocial and educational trajectories, such as those leading toward secondary school graduation. This

theory, however, was developed to explain boys' antisocial behavior in general, not the failure to graduate from secondary school in particular. As a result, it is not clear whether the peer processes described earlier (i.e., peer acceptance at the group level and friends' characteristics at the dyadic level) play an active (i.e., mediating) role in the process leading disruptive and socially unskilled boys to encounter school problems and, ultimately, to fail to obtain a secondary school diploma. In addition, the individual psychological processes that might explain or mediate the hypothesized role of peer experiences with regard to school withdrawal are not clearly defined. The participation-identification perspective described by Finn (1989) specifies which psychological processes may be involved and thus complements the social interactional perspective in explaining how negative peer experiences may contribute specifically to the failure to graduate from secondary school.

### *Psychological and Motivational Antecedents of the Failure to Graduate: Contributions of the Participation-Identification Perspective*

Finn (1989) suggested that students undergo a cycle of academic participation and identification with school during their school years. For most students, active participation in school activities leads to positive academic outcomes (e.g., high academic achievement), which in turn reinforce psychological and emotional identification with school. School identification—described as a feeling of belongingness to the school milieu and as the internalization of the school's goals and values—is thought to be essential to academic perseverance and secondary school graduation.

However, for some students, the participation-identification cycle is disrupted, thereby affecting both academic performance and commitment to schooling. These students may fail to internalize the school's goals and values, increasing the odds of premature school withdrawal and failure to graduate. Negative peer relationships are a potential disrupter of this cycle. For example, ostracism by the peer group may generate aversion for classmates and school

in general (see review by Hymel et al., 1996). Having friends with deviant attitudes and behaviors may also influence boys to behave in deviant ways (Dishion et al., 1995), so that school disengagement might be contagious within deviant peer groups.

### *The Impact of Peer Experiences on Secondary School Graduation*

By combining the variables that were identified as crucial elements in the pathway leading to the failure to graduate from secondary school according to either the social interactional or the participation-identification perspectives, we have developed the comprehensive model presented in Figure 1. As suggested by these theoretical perspectives, peer experiences are depicted as central elements in the developmental pathway leading to disengagement from school and, ultimately, the failure to graduate. Still, much empirical research remains to be done in order to confirm the validity of this model.

One important issue that needs to be addressed is the distinct contributions of different aspects of the peer experience (Furman & Robbins, 1985; Hartup, 1996; Sullivan, 1953). Gifford-Smith and Brownell (2003) suggested that most studies of peer relations have examined a single aspect of this experience (e.g., either peer acceptance or friends' characteristics). However, the only way to uncover the unique effects of different types of peer experiences is to incorporate all of these variables within the same study.

Another issue that deserves special attention has been raised by several authors (e.g., Finn, 1989; Hymel et al., 1996; Rumberger, 1987), who have contended that, even though the correlation between early peer difficulties and school dropout is well established, very little is known about the psychological processes behind this relation. In fact, longitudinal studies often focus on observable (social, behavioral, and academic) variables rather than on the psychological process of disengagement.

In order to address these issues, the current study assessed two distinct types of peer experiences that are likely to contribute to secondary school graduation in boys. These include peer accep-

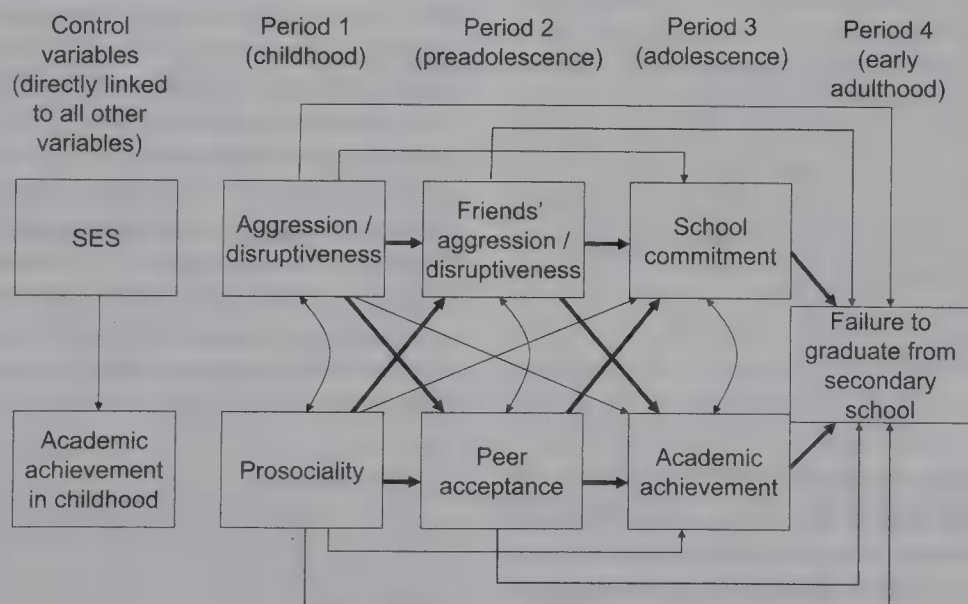

Figure 1. Initial model. Arrows in bold represent the hypothesized indirect (mediation) paths. SES = socioeconomic status.

tance and friends' aggressive behaviors. We also took into account the roles of school commitment and academic achievement as "psychological consequences" of negative peer experiences and, consequently, as proximal precursors of the failure to graduate that could mediate the effects of negative peer experiences (see Figure 1). Other established precursors of graduation were also taken into account as control variables (i.e., SES and early academic achievement).

### Current Study

The longitudinal data used to test the proposed developmental model were collected over several periods of development, including childhood (Period 1), preadolescence (Period 2), adolescence (Period 3), and early adulthood (Period 4).<sup>1</sup>

In Period 1, children's behaviors serve as antecedents of the peer experiences. Specifically, high levels of aggressive-disruptive behaviors as well as low levels of prosocial behaviors are the hypothesized antecedents of low peer acceptance and association with aggressive-disruptive friends in preadolescence (Period 2).

Next, negative preadolescent peer experiences are hypothesized to predict the failure to graduate because they interfere with normal learning activities and contribute to psychological disengagement from school. In other words, peer experiences in preadolescence (Period 2) should predict students' academic achievement and commitment to educational goals and values during adolescence (Period 3). Finally, lower academic achievement and school commitment during adolescence (Period 3) are hypothesized to predict the failure to graduate by early adulthood (Period 4) directly (and act as mediators of the association between negative peer experiences and the failure to graduate).

Lower family SES and academic achievement in childhood are early risk factors for deviant school pathways and, as such, they are used as control variables. In order to perform a more stringent test of mediation, we assumed control variables were related not only to the dependent variable, but also to all other variables in the model.

This study was performed with a community-based sample. However, participants had a relatively high risk of failing to graduate from secondary school, as they were boys recruited from public schools located in low-SES, urban neighborhoods. Indeed, whereas the overall provincial graduation rate for male and female students aged 20 years or less was 71.7% (Education Department, 2001), the rate of graduation among our participants by age 23 was only 53.3%. More precisely, 49.7% of participants graduated without interrupting their schooling, and 3.6% graduated in spite of having temporarily dropped out of school.

### Method

#### Participants

Participants were recruited when they were 6 years old at the end of the 1983–1984 school year, in the context of the Montreal Longitudinal Experimental Study, a larger project aimed at studying the psychosocial development of low-SES, urban boys. This community-based sample initially targeted all boys attending kindergarten in the 53 public schools located in low-SES neighborhoods that were part of the Montreal French school board (Quebec,

Canada). From the 1,161 boys recruited (85.0% of the targeted sample), only the 1,037 boys whose parents were born in Canada and spoke French as a first language were retained in the study. Data on the dependent variable, secondary school graduation by 23 years of age (2001), were available for 98.2% of this sample (1,018 participants). Sixteen participants had died by that time, and 3 had moved out of the country. Because of missing data, the final sample used for the main analysis was composed of 997 participants. (Details on attrition are provided in the Results section.)

#### Measures

All measures were administered in French. Instruments that were only available in English were translated into French and back-translated into English. The back-translations were compared to the original versions of the questionnaires by English-speaking judges who verified that the original meaning was preserved. The timing of assessments and descriptive statistics for all instruments are presented in Table 1. Because the skewness statistic for all variables ranged from  $-0.33$  to  $0.92$ , and kurtosis ranged from  $-1.98$  to  $0.21$ , normality of the data was deemed satisfactory for further analyses.

**SES.** Parents' occupational prestige was computed from their earning and educational levels (Blishen, Carroll, & Moore, 1987). The measure was taken when participants were 6 years old (the 1st year of the study) or at a subsequent year if earning and educational data were not available at the first wave of data collection (see the *Attrition* subsection under the Results section for more details on this imputation procedure). For most participants, a score was available for both parents, so an average score was used.

Blishen et al. (1987) did not mention a specific range of scores for low-SES occupations, but they reported a mean score (42.74) and the standard deviation (13.28) for their instrument. The minimum score on this scale is 17.81, which corresponds to the occupations of newspaper carrier and vendor. The average score for this sample ( $M = 38.45$ ,  $SD = 10.70$ ) is about one-third of a standard deviation below the mean proposed by Blishen et al. It is lower than the mean obtained by a representative sample of boys living in the province of Quebec over the same period ( $M = 42.08$ ,  $SD = 12.09$ ). Examples of occupations that correspond to the average SES score for the current sample are orderlies, mail and postal clerks, and machine tool operators.

**Academic achievement in early elementary school years.** Elementary school teachers reported on students' academic achievement in French (first language) and mathematics in 1985 and 1988 (when the students were ages 7 and 10), which correspond to Grades 1 and 4 for students in age-appropriate classrooms. In order to increase the reliability of the scores obtained from this measure, an average score of academic achievement over the 2 years was computed to represent academic achievement in childhood. For the participants with missing data at one of these assessments (28.3%

<sup>1</sup> Several participants were retained in lower grades: The rate of retention was 10.9% by the end of Grade 1 and tended to increase in subsequent years. Therefore, to be consistent with the developmental periods being studied, data were gathered for each participant at every year, even for those who were in lower grades. Nevertheless, for the sake of simplicity, only the school grades for participants in age-appropriate classrooms are reported in the *Measures* section.

Table 1  
*Age(s) at Assessment, Indices of Central Tendency, and Distributional Properties of Study Measures*

Measure	Age(s) at assessment (years) <sup>a</sup>	N	M	SD	Skewness	Kurtosis
Control variables

Period 4						
Failure to graduate	23	981	0.54	0.50	-0.15	-1.98

Note. SES = socioeconomic status.

<sup>a</sup>Where more than one age is listed, the mean score over several assessments was used.

of the final sample), we used the value obtained at the other assessment so they did not have to be excluded from the analyses due to missing data. Final scores ranged on a continuous scale from 0 (*academic failure*) to 4 (*excellent academic performance*). A correlation of .53 ( $p < .001$ ) was found for academic achievement in Grades 1 and 4 and was based on participants with complete data at both times of measurement (64.2% of the total sample).

*Participants' behavior in early elementary school years.* Kindergarten and elementary school teachers reported on students' aggressive-disruptive behaviors and on their prosocial behaviors in 1984 and 1988 (when the students were ages 6 and 10), which correspond to kindergarten and Grade 4 for students in age-appropriate classrooms, using the Social Behavior Questionnaire (Tremblay, Desmarais-Gervais, Gagnon, & Charlebois, 1987; Tremblay, Vitaro, Gagnon, Piché, & Royer, 1992). Aggression-disruptiveness was assessed with items such as "This child bullies," "This child kicks, bites or hits," and "This child is restless and cannot stand still," and prosociality was assessed with items like "This child praises other students" and "This student helps clear up a mess," which were rated 0 (*never*), 1 (*sometimes*), or 2 (*often*). Scores on the 13-item aggression-disruptiveness scale ranged from 0 to 26, with higher scores representing frequent occurrences of aggressive-disruptive behaviors. Cronbach's alphas for this scale were .93 for the kindergarten assessment and .92 for the Grade 4 assessment. Scores on the 10-item prosocial scale ranged from 0 to 20, with higher scores representing frequent occurrences of prosocial behaviors. Cronbach's alphas for this scale were .92 for the kindergarten assessment and .91 for the Grade 4 assessment. Correlations of .47 ( $p < .001$ ) and .23 ( $p < .001$ ) were found between kindergarten and Grade 4 scores for aggressive-disruptive and prosocial behaviors, respectively, and were based on participants with complete data at both times of measurement (94.2% and 94.0% of the total sample, respectively). In order to increase the reliability of the scores obtained from these measures, the average score over the 2 years was used for each scale. For participants with missing data at one of these assessments, we used the value obtained at the other assessment.

*Peer experiences in late elementary school years.* Measures of peer experiences were based on scores obtained in 1989 and 1990 (when the students were ages 11 and 12), which correspond to Grades 5 and 6 for children in age-appropriate classrooms. Again, these measures were averaged over the 2 years.

For peer experiences at the group level, a measure of peer-perceived acceptance in the peer group was used. Scores on two items, namely, "Those who are liked by everyone" and "Those who have very few friends," were combined to create this variable. These items were part of the Pupil Evaluation Inventory (PEI; Pekarik, Prinz, Liebert, Weintraub, & Neale, 1976) that was administered to all children in the classrooms attended by the participants. For each item, students could nominate up to four classmates. The total number of nominations received by each participant on every item was standardized within their classroom. A correlation of .65 ( $p < .001$ ) was found for peer acceptance in Grades 5 and 6 and was based on participants with complete data at both times of measurement (74.9% of the total sample).

For measures of dyadic peer experiences, participants' friends were identified using reciprocated nominations on the item "Those who are your best friends" from the PEI questionnaire. Then, friends' scores on the 20-item aggression-disruptiveness scale of the PEI (including items like, "Those who start a fight over nothing" and "Those who disturb other students who are trying to work") were used to assess their level of aggressive-disruptive behaviors. Cronbach's alphas for this scale were .97 for the Grade 5 assessment and .96 for the Grade 6 assessment. For participants with more than one reciprocated friend, an average score for all friends was computed. The 303 participants (30.4%) who had no reciprocated friends at both assessments did not have to be excluded altogether from the main analyses, as the full information maximum likelihood method was used to manage missing data. More information on this procedure is provided in the *Attrition* subsection under the Results section. A correlation of .22 ( $p < .001$ ) was found for reciprocated friends' scores of aggression-disruptiveness in Grades 5 and 6 and was based on participants with complete

data on their reciprocated friends' characteristics at both times of measurement (38.4% of the total sample).

*Academic achievement and school commitment during secondary school.* Teachers reported on students' academic achievement in French (first language) and mathematics from 1992 through 1995 (when the students were ages 14 through 17), which correspond to Grades 8 through 11 for students in age-appropriate classrooms.<sup>2</sup> An average score of academic achievement in French and mathematics across the 4 years was computed to represent academic achievement during adolescence. Final scores ranged on a continuous scale from 0 (*academic failure*) to 4 (*excellent academic performance*). Correlations between scores of academic achievement for all pairs of assessments over this 4-year period ranged from .29 to .58 ( $p < .001$ ). The proportion of participants with complete data on each pair of assessments ranged from 60.3% to 76.9% of the total sample.

School commitment was measured through self-reports with a seven-item scale including such statements as "How much does having good grades matter to you?" and "How long do you intend to stay in school?" Once again, an average score, based on all available data gathered from 1992 through 1995 (when the students were ages 14 through 17), was used. Each item was rated on a scale ranging from 1 to 4 (total scores ranging from 7 to 28), with higher scores reflecting higher school commitment. Cronbach's alphas for this scale ranged from .67 to .71, depending on the year of assessment. Correlations between scores of school commitment for all pairs of assessments over this 4-year period ranged from .47 to .69 ( $p < .001$ ). The proportion of participants with complete data on each pair of years ranged from 63.6% to 77.4% of the total sample.

*Graduation from secondary school.* Data on graduation status by early adulthood (when the students were age 23; December 2001) were available from the Education Department's official records. Although the normal age of graduates in the province of Quebec is 17 years, temporary dropout and grade retention delayed the time of graduation for several students. In the current sample, only 32.2% of the participants were placed in regular, age-appropriate classrooms by the time they reached their final year of secondary schooling, and 11.2% of the participants were 1 year behind. The remaining 56.6% of the participants were 2 or more years behind grade level, had been placed in special classrooms for students with learning or behavioral difficulties, or had dropped out of secondary school. Still, by 23 years of age, 26.3% of this final group had graduated (89.9% of students who were no more than 1 year behind had graduated by age 23). According to Bowlby and McMullen (2005), the probability of completing secondary schooling has dramatically decreased by 20 to 24 years old. Age 23 is thus an appropriate time for measuring graduation status, as this status is likely to be definitive for most participants.

### Procedure

Participants were recruited around the end of their kindergarten year (in the spring of 1984). With the collaboration of 53 public schools located in low-SES areas of Montreal and its immediate surroundings, we sent questionnaires to the parents of all boys attending kindergarten at those schools. A consent form explaining the study was sent in the same package and had to be signed and returned by mail along with the questionnaire. This procedure was

repeated every year, and parents were informed that their son would fill out questionnaires at school when that was the case. For each participant, one teacher filled out a questionnaire assessing the student's behavior and academic achievement at every year.

### Results

Structural equation modeling (SEM) was used to assess the fit of the model presented in Figure 1. Attrition, intraclass correlations (to assess between-schools effects), and bivariate correlations among the main measures are presented first.

#### Preliminary Analyses

*Attrition.* The use of SEM allowed for the inclusion of all participants having complete data on exogenous variables, even if they had missing data on other variables. In the current model, SES was the only exogenous variable. It was therefore important to minimize the number of participants with missing data on this particular variable. Data on SES at the first wave of data collection (1984) were available for 973 participants, but given that the correlation between SES in 1984 and the same variable measured in subsequent years was high (ranging from .62 to .67), available data from the nearest following year (1988, 1989, or 1990) were used for participants with missing values in 1984. Using this strategy, only 40 participants were lost due to missing data. Thus, 997 participants out of the 1,037 initially recruited could be included in the primary analysis using SEM, preserving 96.1% of the initial sample.

Excluded participants had significantly lower academic achievement in elementary school,  $t(967) = -3.93, p < .001$ , lower levels of prosocial behaviors,  $t(1035) = -2.82, p < .01$ , lower school commitment in secondary school,  $t(901) = -2.09, p < .05$ , and lower academic achievement in secondary school,  $t(896) = -3.19, p < .01$ , than participants who were included in the primary analysis. A chi-square test also revealed that excluded participants tended to be less likely to graduate from secondary school, although this difference was only marginally significant,  $\chi^2(1, N = 1,018) = 3.67, p = .06$ . However, no significant differences emerged on their levels of aggressive-disruptive behaviors in childhood, their friends' levels of aggressive-disruptive behaviors, and their levels of peer acceptance.

Missing data on endogenous variables were handled using the full information maximum likelihood method. Therefore, the covariance matrix was constructed from all available information for each participant. Complete data on each relevant pair of variables ranged from 67.8% to 100.0% of the final sample ( $N = 997$ ), with an average of 86.5%.

*Intraclass correlations.* Because participants were recruited from different schools, intraclass correlations were computed in order to verify whether some of the variance in the main variables of the model (i.e., participants' behaviors in childhood, peer experiences in preadolescence, academic achievement and school commitment in adolescence, and failure to graduate) could be

<sup>2</sup> In contrast with the school systems in other Canadian provinces and in the United States, secondary schooling in the province of Quebec lasts only 5 years, thus ending in Grade 11. As a result, students normally enter secondary school at 12 years old and graduate at 17 years old.

attributed to a higher order "school effect." These analyses revealed that a significant proportion of variance in these variables was attributable to school. Effect sizes were small to moderate (Hox, 2002), ranging from 4% (for aggressive-disruptive behaviors in childhood) to 11% (for failure to graduate). Although the hierarchical structure of the data may suggest that a multilevel analytic framework is desirable, the distribution of the participants into 197 different institutions after the transition to secondary school entails some restrictions with regard to the application of a multilevel analytical procedure. In fact, the small number of participants per school—50% of the schools included only 1 participant, and only 25% of schools included 5 or more participants—made implementing a multilevel framework inadvisable (Newsom & Nishishiba, 2002).

**Bivariate correlations.** Correlations, which are presented in Table 2, were all in the expected direction. First, SES was positively related to academic achievement, prosocial behavior, peer acceptance, and school commitment but negatively related to participants' aggressive-disruptive behaviors and failure to graduate. However, SES was unrelated to friends' level of aggressive-disruptive behaviors.

Still in line with the hypotheses, academic results in childhood were negatively correlated with concurrent aggressive-disruptive behaviors but positively associated with prosocial behaviors. In addition, boys with higher levels of academic achievement in childhood tended to associate with less aggressive-disruptive friends in preadolescence. They also tended to have higher levels of peer acceptance in preadolescence, higher levels of school commitment and academic achievement during adolescence, and lower risks of the failure to graduate.

Aggressive-disruptive behavior in childhood was negatively correlated with prosocial behaviors. Boys who were more aggressive-disruptive in childhood tended to associate with aggressive-disruptive friends and to have low levels of peer acceptance in preadolescence. Early aggression-disruptiveness was also related to low levels of adolescent school commitment and academic achievement and to the failure to graduate from secondary school. Prosocial boys tended to experience greater peer ac-

ceptance and to have friends with lower levels of aggressive-disruptive behaviors in preadolescence. Prosociality was also related to higher levels of school commitment and academic achievement during adolescence as well as to a lower risk of the failure to graduate.

No correlation emerged between peer acceptance and the concurrent level of friends' aggressive-disruptive behaviors. Still, having more aggressive-disruptive friends in preadolescence predicted lower levels of adolescent school commitment and academic achievement as well as a greater risk of the failure to graduate. In contrast, greater peer acceptance in preadolescence predicted greater adolescent school commitment and academic achievement as well as a lower risk of the failure to graduate.

Finally, greater school commitment was positively related to academic achievement in adolescence. Both commitment and academic achievement were inversely related to the failure to graduate.

### Model Testing

All analyses were conducted with *Mplus* Version 3.01 (Muthén & Muthén, 2004) using weighted least squares estimation. We first examined the fit of a baseline model in which all variables were completely unrelated. The fit of this model was very poor,  $\chi^2(20, N = 997) = 1,050.45, p < .001$ . (In SEM analyses, a good model fit usually yields a nonsignificant chi-square statistic). We then tested our hypothesized model in order to assess any improvements in fit.

The hypothesized model ( $M_1$ )—a saturated model—was tested first. Some of the hypothesized paths were not significant and were therefore removed in order to build a more parsimonious model. The final model,  $M_2$ , is illustrated in Figure 2, with standardized coefficients for all significant paths. Arrows in bold indicate significant indirect pathways. Fit indices suggest that this model fits the data very well,  $\chi^2(10, N = 997) = 8.57, p = .57$ , comparative fit index = 1.00, Tucker-Lewis index = 1.00 (comparative fit index and Tucker-Lewis index values above .95 are indicative of a good fit). The nonsignificant chi-square value of the final model

9. Failure to graduate	-.35***	-.54***	.36***	-.18***	.12**	-.18***	-.41***	-.50***	—

Note. Period 1 corresponds to childhood (ages 6 or 7 and 10 years), Period 2 corresponds to preadolescence (ages 11 and 12 years), Period 3 corresponds to adolescence (ages 14 through 17 years), and Period 4 corresponds to early adulthood (age 23 years). SES = socioeconomic status.  
\* $p < .05$ . \*\* $p < .01$ . \*\*\* $p < .001$ .

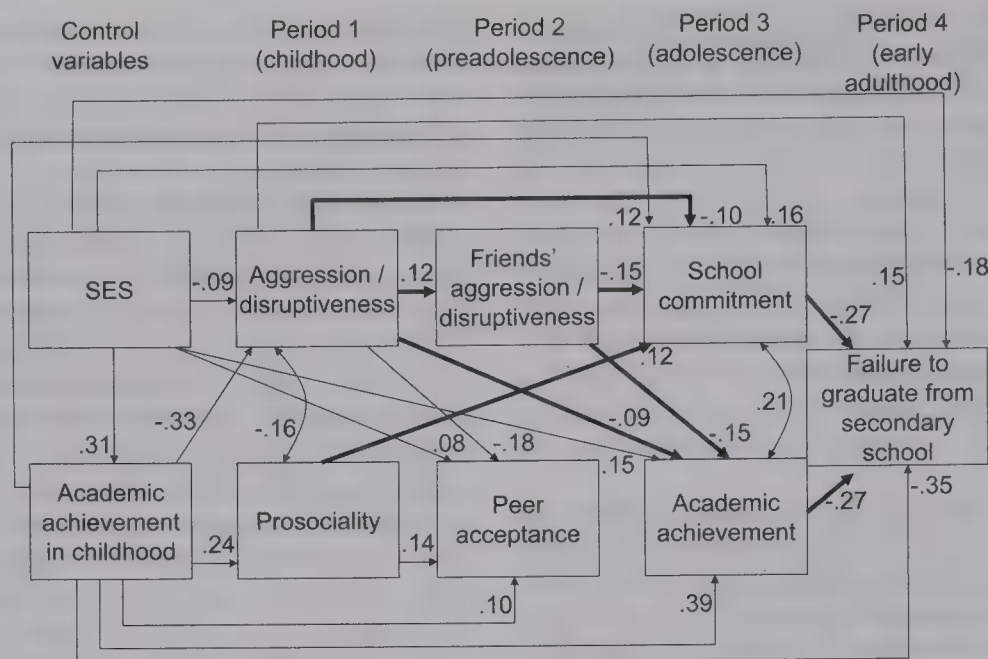

Figure 2. Final model. Numbers indicate significant standardized covariance estimates. Arrows in bold indicate indirect paths. SES = socioeconomic status.

( $M_2$ ) suggests that the original, saturated model ( $M_1$ ) does not fit the data significantly better than does the more parsimonious model ( $M_2$ ).

**Direct paths.** In line with the hypotheses, most of the direct paths included in the initial model were statistically significant.

First, SES was a significant predictor of childhood academic achievement. In line with our hypotheses, higher SES predicted lower levels of childhood aggressive-disruptive behavior, higher preadolescent peer acceptance, and higher adolescent academic achievement and school commitment. Higher SES was associated with lower odds of the failure to graduate.

Higher levels of the other control variable, childhood academic performance, predicted lower levels of aggressive-disruptive behavior and higher prosociality in childhood. It also predicted higher preadolescent peer acceptance and higher adolescent academic achievement and school commitment. Finally, it was negatively associated with the failure to graduate.

Childhood aggression-disruptiveness was negatively associated with concurrent levels of prosociality. It was positively associated with friends' preadolescent aggression-disruptiveness and negatively associated with preadolescent peer acceptance. Higher levels of childhood aggression-disruptiveness were associated with lower adolescent academic achievement and school commitment, and it was a significant predictor of the failure to graduate. In contrast, childhood prosociality predicted higher preadolescent peer acceptance and adolescent school commitment.

As revealed by the preliminary bivariate analyses, preadolescent peer acceptance and friends' aggression-disruptiveness were not significantly intercorrelated. Friends' preadolescent aggression-disruptiveness predicted lower levels of adolescent academic achievement and school commitment. However, in contrast to the bivariate analyses, preadolescent peer acceptance was not related to the hypothesized adolescent mediators (i.e., school commitment and academic achievement).

Finally, both adolescent mediators, school commitment and academic achievement, were significantly and positively intercor-

related. They were associated with lower odds of the failure to graduate.

**Indirect paths.** The principal objective of this study was to determine whether peer experiences played an active (i.e., mediating) role in the pathways leading to the failure to graduate from secondary school. We tested a number of indirect paths in which peer experiences were hypothesized (a) to relate to the failure to graduate via school-related variables in adolescence and (b) to mediate the association between childhood behaviors and the adolescent precursors of the failure to graduate.

Eight indirect paths were modeled in order to reflect all possible indirect pathways from childhood aggressive-disruptive and prosocial behaviors to the failure to graduate from secondary school in adulthood via friends' aggressive-disruptive behaviors and peer acceptance in preadolescence and subsequent adolescent school commitment and academic achievement. In addition, we tested four indirect paths from childhood aggressive-disruptive and prosocial behaviors to the failure to graduate that included school commitment and academic achievement as mediators but excluded the peer experiences. This procedure was used to minimize the risk of overestimating the variance attributed to the indirect paths that included the peer experiences.

The final model revealed support for two of the eight possible indirect paths involving peer experiences. First, as illustrated in Figure 2 by the bold arrows, the path starting from participants' aggressive-disruptive behaviors and running through friends' aggressive-disruptive behaviors as well as school commitment was significant, although the standardized coefficient for this pathway was small (.01). The other significant indirect path started from participants' aggressive-disruptive behavior, which led to friends' aggressive-disruptive behaviors, adolescent academic achievement, and finally, the failure to graduate (standardized path coefficient = .01). Peer acceptance was not a mediator in any pathway linking early behavior to the failure to graduate.

It is noteworthy that in addition to the role played by aggressive-disruptive behavior in childhood in the above-mentioned indirect

pathways involving friends' aggressive-disruptive behavior, participants' aggression-disruptiveness was also related to the failure to graduate through other pathways. For example, childhood aggression-disruptiveness was directly related to adolescent school commitment which, in turn, predicted the failure to graduate (standardized path coefficient = .03). Childhood aggression-disruptiveness was also related to adolescent academic achievement which, in turn, predicted the failure to graduate (standardized path coefficient = .02).

One additional indirect path—from prosocial behavior in childhood to school commitment to the failure to graduate—explained a significant proportion of variance in this outcome (standardized path coefficient = -.03).

## Discussion

The current study was meant to test a comprehensive model of the failure to graduate from secondary school in which two types of peer experiences—peer acceptance and friends' aggressive-disruptive behavior—were hypothesized (a) to be independent and significant predictors of the failure to graduate and (b) to play a mediating role in the path from early behavior to the failure to graduate. Specifically, as suggested by the social interactional perspective, peer experiences were embedded into a chain of events occurring over several developmental periods and were hypothesized to be predicted by behavior patterns in childhood. Also, according to the participation-identification perspective, two proximal predictors of the failure to graduate were hypothesized to mediate the link between peer experiences during preadolescence and secondary school graduation, including school commitment and academic achievement during adolescence.

### *SES, Early Academic Performance, and Childhood Behavior Patterns*

Although peer experiences were the central variables in our model, several of the links among variables that were included in the model for control purposes were significant and warrant attention. First, as expected, SES had a significant direct and negative relationship with the failure to graduate. As explained earlier, parents' behaviors and expectations, together with the lack of family resources, are potential mediators of this link. However, these variables were not included in the study, which might account for the residual link between SES and the failure to graduate.

Second, poor academic achievement in the early elementary school years was found to predict the failure to graduate over and above academic achievement in secondary school. Although proximal measures of a given variable (in this case, academic achievement in secondary school) are usually expected to be stronger predictors of the outcome, the current study shows that this is not always true. Our finding, however, makes sense from a developmental psychopathology perspective. Early schooling experiences initially direct students along an academic trajectory and may lead to a range of events that keep students on that particular path. In the current study, poor academic achievement during the first years of schooling not only was the strongest direct predictor of the failure to graduate but also contributed to other variables in the model (i.e., participants' aggressive-disruptive and prosocial behaviors in childhood and academic achievement and commitment

in secondary school). Early academic difficulties might be stronger predictors of the failure to graduate than later difficulties because they affect young children's school-related self-esteem and self-efficacy as well as their relationships with school staff. In contrast, academic difficulties that emerge in secondary school may simply precipitate school dropout in some students without affecting students' deeper beliefs in their academic abilities or capacity to graduate if they ever wish to complete the secondary school program.

Third, a significant, direct link was found between aggressive-disruptive behaviors in childhood and the failure to graduate by early adulthood. This link, which was also found in several empirical studies, cannot be entirely explained by ensuing peer difficulties. Other mediators should therefore be explored in future studies. For example, being more aggressive and disruptive than other students may be the first step in a developmental pathway toward the failure to graduate because such behaviors affect students' relationships with teachers. These students may not receive the same amount of help, support, and encouragement in their schoolwork (Brendgen, Wanner, Vitaro, Bukowski, & Tremblay, 2007).

In contrast to participants' levels of aggression-disruptiveness, no residual link emerged between prosociality in childhood and the failure to graduate from secondary school. The contribution of low prosociality to the failure to graduate was therefore entirely mediated by school commitment in adolescence. This suggests that prosocial behaviors in school may be an early indicator of a student's stable tendency to conform to social norms and expectations. In addition, this finding could indicate that prosocial children are more likely to have positive experiences in school (e.g., being praised by the teacher) that help them identify with the institution.

### *The Role of Aggressive-Disruptive Friends*

In partial support of our hypotheses, two of the indirect pathways involving the association with aggressive-disruptive friends during preadolescence were significant. Indeed, both pathways starting from aggression-disruptiveness in childhood and running through friends' aggressive-disruptive behavior during preadolescence were significant. The first pathway contributed to school graduation through the link between friends' behavior and school commitment, whereas the second pathway reached school graduation through the link between friends' behavior and academic achievement. These findings support the validity of our integrative theoretical model, in which variables from the participation-identification perspective (i.e., school commitment and academic achievement) effectively complement the social interactional framework.

In contrast, the indirect pathways involving prosocial skills in childhood, peer experiences, and graduation status by early adulthood were nonsignificant. This is surprising, given that a lack of prosocial skills has been hypothesized to contribute to negative peer experiences to the same degree as aggressive-disruptive behaviors (Patterson et al., 1989). Still, we found an indirect pathway starting from low prosociality in childhood and predicting the failure to graduate through its link with low school commitment in adolescence. It seems possible that other types of peer-related problems that were not measured in the current study, such as

friendlessness or an association with friends who are deviant but not aggressive-disruptive (e.g., friends who are truant or who cheat on exams but who are not disruptive in the classroom and who do not get involved into fights), are involved in this indirect pathway.

In line with this suggestion, future studies should extend their measures of friends' characteristics to include not only negative, but also positive traits, as previous research has shown that friends can play a positive role in the context of students' school adjustment (Berndt, Hawkins, & Jiao, 1999; Berndt & Keefe, 1995; Chen, 2005; Mounts & Steinberg, 1995; Wentzel, Barry, & Caldwell, 2004). For example, affiliating with friends who have developed positive attitudes toward school and authority figures, who intend to undertake postsecondary education, and who display good study habits is likely to predict later secondary school completion. Affiliation with such friends could also protect vulnerable students against school disengagement and the failure to graduate.

The current study's results suggest that parents of preadolescent boys who are at risk for the failure to graduate can promote their sons' successful completion of the secondary school program by monitoring the boys' social activities during preadolescence. Although parents often allow their children to spend more time with their friends in unsupervised settings as they grow older, mothers and fathers should at least get to know their children's friends and encourage associations with those who do not display excessive levels of aggression and disruptiveness. This is especially important in the case of boys who have a personal history of aggressive-disruptive behavior or who displayed low levels of academic achievement in elementary school.

Furthermore, because many friendships arise in the school setting, teachers are in a very good position to identify potentially risky associations between aggressive-disruptive youngsters. Teachers should work together with parents to encourage at-risk students to become friends with well-adapted students who, in addition to being positive role models, may also be able to actively discourage deviant behaviors and negative attitudes toward school. School administrators can contribute to this end by providing a variety of extracurricular activities through which at-risk students can meet and develop friendships with normative peers in adult-supervised settings.

### *The Role of Peer Acceptance*

In contrast to the positive results obtained for the other type of peer experience, the role of peer acceptance as a fundamental element in the developmental pathway leading to school graduation was not supported by the current study. Still, peer acceptance should not be dismissed as a potential contributor to school graduation.

First, the timing of measurement might explain the failure of peer acceptance to play a role in the pathway leading to school graduation. In fact, although peer acceptance should, according to some authors (Buhrmester & Furman, 1986), contribute to psychological adjustment even after childhood, others suggested that peer acceptance is most important during the first years of schooling. In contrast, dyadic peer experiences (such as the association with aggressive-disruptive friends) are most important in preadolescence or adolescence, according to this second group of authors (Patterson et al., 1992; Sullivan, 1953).

Second, as suggested by the social interactional perspective, early peer rejection may pave the way for later involvement with aggressive-disruptive friends. To test for this possibility, future studies of the developmental processes leading to secondary school graduation should adopt a strategy that would pit two models against one another. In one model, peer acceptance and association with aggressive-disruptive friends would act on future adjustment in a parallel manner. In the alternative sequential model, peer rejection would predict subsequent associations with deviant friends, which would in turn predict school adjustment problems in early adulthood. Comparing these two models would require the assessment of both types of peer experiences throughout childhood and adolescence. As we did not measure peer experiences before and after preadolescence, such a model could not be tested in the current study.

A third explanation for the nonsignificant results obtained with peer acceptance is that the operationalization of this variable might have failed to represent the construct it was meant to measure. In fact, in the theories proposed by Sullivan (1953) and by Patterson and his colleagues (1992), peer acceptance corresponds to being well-liked by one's peers. Students' positive feelings toward one another are best measured with a procedure of like-most and like-least peer nominations (e.g., Coie, Dodge, & Coppotelli, 1982; Newcomb & Bukowski, 1983). In the current study, however, peer acceptance was evaluated through peer nominations of students having many friends and of those having very few friends. According to Parkhurst and Hopmeyer's (1998) criteria, this procedure may be closer to an assessment of "peer-perceived popularity," rather than "sociometric popularity." In other words, our measure probably reflected the extent to which classmates considered our participants as popular and high in social status, rather than their true feelings of liking toward our participants. Indeed, Parkhurst and Hopmeyer found that peer-perceived popularity is a correlate of social dominance, and although some students who get high ratings on this measure are perceived as kind and trustworthy by their peers, many others are perceived as aggressive and "stuck-up." Other researchers who measured peer-perceived popularity by asking participants to rate their classmates on a 5-point scale ranging from *not at all popular* to *very popular* found that increases in this variable over four academic semesters were related to decreases in academic achievement over the same period of time, but only in highly aggressive adolescents (Schwartz, Gorman, Nakamoto, & McKay, 2006). In contrast, Ollendick, Weist, Borden, and Greene (1992) reported that a rejected status, measured through sociometric nominations, was associated with a higher risk of dropping out of school by Grade 9.

It is noteworthy that the significant results obtained with friends' aggressive-disruptive behaviors and the nonsignificant results obtained with peer acceptance may suggest the existence of a third variable effect—also known as a spurious or incidental effect (Ladd & Troop-Gordon, 2003; Woodward & Fergusson, 2000). In fact, one might put forward the hypothesis that any significant relationship between peer acceptance and later school adjustment found in previous studies was a mere reflection of the true relationships existing between two correlates of peer acceptance, namely, friends' aggressive-disruptive behaviors and school adjustment. However, a significant relationship between friends' aggression-disruptiveness and peer acceptance would have been necessary to support such an explanation, and because the corre-

lation between these variables was null (even in the bivariate analyses), there is little support for the third variable hypothesis.

### Limitations

First, some of the variables that may relate to graduation were not included in the model, and this limits our understanding of the overall process leading to the failure to graduate. This study focused on peer acceptance and friends' aggression-disruptiveness as key potential predictors of the failure to graduate. Therefore, other peer-related variables were not addressed here, including victimization by peers, crowd affiliation (i.e., the identification with a reputation-based group of peers like the "popular students," the "druggies," or the "brains"), clique membership (i.e., the association with a group of close friends sharing similar traits, values, and activities), clique-related status (e.g., central or peripheral), friendlessness, and friendship quality. These variables represent a range of peer experiences that could be related to concurrent and future academic outcomes.

In addition to peer-related variables, family-related variables may also enrich our understanding of the factors that influence graduation outcomes. This study incorporated only family SES. Yet, as suggested by the social interactional perspective, other family variables may influence graduation status, including parental supervision—especially at the time when children enter adolescence and become more independent from parents (Patterson et al., 1992). Other researchers have called attention to the quality of early parenting and home environment (Jimerson, Egeland, Sroufe, & Carlson, 2000), as well as to parents' involvement in their children's schooling, expectations for their children's educational attainment, encouragement of the children's achievement, relationships with school staff, and participation in school activities as potential predictors of later academic outcomes (Astone & McLanahan, 1991; Kohl, Lengua, & McMahon, 2000).

The social interactional perspective also suggests that the establishment of a positive relationship with the teacher may contribute to students' school adjustment (Brendgen et al., 2007; Pianta & Stuhlman, 2004). Further, recent reviews point to structural and human characteristics of the school that may influence graduation rates (e.g., school and class size; the availability of alternative academic curricula for potential dropouts; the valuing of work and learning; the adequacy of educative materials; positive relationships among school staff members, parents, and students; and the availability of extracurricular activities; Baker et al., 2001; Rutter & Maughan, 2002). These hypothesized relations are also consistent with the participation-identification view, inasmuch as a positive school climate is thought to encourage active participation in school activities and should make it easier for students to identify with the institution's goals and values (Finn, 1989).

Second, the methodological limitations of this study also deserve some consideration. This study focused on a high-risk population: boys from low-SES, urban neighborhoods. Although it is important to understand the pathway toward the failure to graduate taken by these vulnerable students, this limits the generalizability of our findings. More research will be necessary in order to verify whether the current findings are also true for girls, for students of other ethnic groups, for youngsters living in medium-to-high-SES neighborhoods, and for those living in rural or semirural areas.

As previously mentioned, the nested structure of our sample (i.e., clusters of students recruited from several schools) raises questions about the comparability of the school experience across participants attending different institutions. The significant intra-class correlations reported in the Results section support the idea that school characteristics may, to some extent, influence students' academic achievement, school behaviors, attitudes toward schooling, and ultimately, chances of graduating. Future studies involving several schools should therefore include a sufficient number of participants per school to allow for a more thorough investigation of the schools' contributions to students' developmental trajectories through multilevel modeling.

In addition, the current study tested a hybrid model based on the combination of sequential and parallel mediation pathways. Such longitudinal studies aid in the elucidation of long-term developmental processes, including those leading to school graduation. Currently, however, bidirectional models (also known as cross-lagged or transactional models) are becoming increasingly popular as researchers recognize that the chain of events leading to a particular developmental outcome is likely to be much more complex than a simple "A causes B which causes C" relationship. Although short-term longitudinal models involving reciprocal effects among variables have been tested (e.g., Welsh, Parke, Widaman, & O'Neil, 2001), long-term longitudinal models of this kind are still scarce. The database used in the current study did not allow us to test for reciprocal effects because many of the relevant variables were not measured at all developmental periods. Nevertheless, future studies based on more recent data sets can answer important questions regarding the short-term, bidirectional mediation processes that comprise the larger pathway toward secondary school graduation.

The issue of missing data is inherent to longitudinal study designs. In the current study, we addressed the issue by using all available data over a specific developmental period for most of the variables. More specifically, average scores based on two assessments were used for the variables measured in Periods 1 and 2, and average scores based on four assessments were used for the variables measured in Period 3. Still, this strategy has its own drawbacks. Although correlations between the scores obtained at different assessments were highly significant, the size of the correlation was quite small for the prosociality measure. Because children's prosociality scores had a general tendency to drop between kindergarten and Grade 4, it seems plausible that the measure of prosociality itself was not equally suitable for measuring this variable at both ages—possibly because the behavioral manifestations of prosociality differ in younger and older children. Low correlations were also found for the measure of aggression-disruptiveness in participants' reciprocated friends over a 1-year interval. Because this measure was based on peer nominations and standardized within classrooms, the low correlation between the two assessment points probably reflects construct instability—that is, the formation of new friendships with students having different levels of aggression-disruptiveness. Aggregating weakly correlated measurements of the same construct may have negatively affected the power of the SEM analysis.

One last limitation of this study concerns the small effect sizes of the significant indirect pathways. The standardized path coefficients of these indirect pathways were all below .10, which is the benchmark for a small effect size (Cohen, 1988). These small

effect sizes were not unexpected given that many mediators were included in the model. Still, every student had his own history of social and academic experiences. Each significant pathway is thus likely to be a worthwhile explanation of the course taken by a small but significant number of individuals during their academic careers, so the indirect pathways presented here should not be dismissed simply on the basis of their small effect sizes. The limited reliability of the scores obtained for some variables (i.e., participants' prosociality and friends' aggression-disruptiveness), as previously discussed, may also have contributed to small effect sizes.

## Conclusion

The current study sheds new light on peers' contribution to the developmental pathway leading to the failure to graduate. In particular, this research highlighted the negative relation between reciprocated friendships with aggressive-disruptive peers and the likelihood of secondary school graduation, which can be attributed to the mediating roles of school commitment and academic achievement.

Although the many questions raised in the Discussion show that much research still needs to be done in order to achieve a full understanding of the role of peer experiences on the pathway leading to secondary school graduation, the current study can inform the development of experimental prevention programs aimed at promoting secondary school completion. The clear association of early academic failure and behavior problems with the failure to graduate from secondary school suggests that interventions should target the development of social skills and school readiness before school entry (e.g., Schweinhart, Barnes, & Weikart, 1993). Furthermore, experimental prevention programs represent good settings to develop strategies that will help at-risk preadolescent students form and maintain friendships with normative peers, perhaps by teaching at-risk preadolescents more appropriate social skills (Asher, Parker, & Walker, 1996) and by involving at-risk students in extracurricular activities that are supervised by well-trained adults and in which well-adjusted youngsters are also taking part (Silver & Eddy, 2006).

Finally, because not all at-risk students have access to structured prevention programs, parents and teachers should be encouraged to monitor closely the peer relationships of at-risk boys and to offer these students opportunities to make friends with normative, prosocial peers. This might be just what it takes for some students to get on the pathway to secondary school graduation, thereby reducing their risk of future psychosocial maladjustment.

# Control, Motivation, Affect, and Strategic Self-Regulation in the College Classroom: A Multidimensional Phenomenon

Duane F. Shell  
University of Nebraska—Lincoln

Jenefer Husman  
Arizona State University

This study of 397 undergraduate students examined relations between self-reported control, goal orientation, future time perspective, affect, and strategic self-regulation. Five patterns were found in three canonical dimensions. The high end of bipolar Dimension 1 linked high self-regulated strategy use and study effort to high self-efficacy, outcome expectancy, and effort causal attribution; high mastery and performance approach and low work avoidance goal orientations; and positive affect. The low end of Dimension 1 linked low strategy use and effort to low self-efficacy, outcome expectancy, and effort causal attribution; high work avoidance goal orientation; and low affect. The high end of bipolar Dimension 2 linked knowledge-building strategies, but not active self-regulation or study effort, to high self-efficacy, outcome expectancy for learning but not grades, and affect causal attribution; high mastery goal orientation; and positive affect. The low end of Dimension 2 linked surface learning, consisting of active self-regulation and study effort but not personal knowledge building, to high effort causal attribution but low self-efficacy and outcome expectancy. Unipolar Dimension 3 linked learned helplessness to high outcome expectancy and external causal attribution but low self-efficacy; high work avoidance goal orientation; and high negative affect and anxiety.

*Keywords:* self-regulation, control beliefs, motivation, strategic learning, affect

The role of motivation in fostering students' self-regulated, strategic learning and academic performance has become an increasingly important topic in cognitive and educational psychology (e.g., Bandura, 1997, 2001; Boekaerts, Pintrich, & Zeidner, 2000; Pintrich, 2003; Pintrich & Schunk, 2002; Wigfield & Eccles, 2002; Zimmerman & Schunk, 2001). Current studies of motivation in academic achievement and self-regulated learning have been framed primarily within the broad context of achievement motivation as it has been extended from early conceptions by theorists such as Atkinson (1964) and Rotter (1966). In this tradition, personal beliefs are seen as one of the primary mechanisms affecting the motivation to engage and persist in self-regulatory and achievement-related behaviors.

Among the many beliefs and constructs identified within the motivational literature (see Pintrich, 2003), beliefs about control are some of the oldest and most examined (Pintrich, 2003; Skinner, 1996; Weisz & Stipek, 1982). Control beliefs concern the extent to which persons believe they can control or influence their environment to attain desired outcomes (e.g., Skinner, 1996). As well as constituting a distinct theoretical field, beliefs about control are thought to interact with other motivational constructs, such as goal

orientation and affect (Skinner, 1996; Pekrun, Elliot, & Maier, 2006; Walls & Little, 2005), and are central to many comprehensive theories of motivation and self-regulation, including social-cognitive theory (Bandura, 1997, 2001; Zimmerman, 2004) and self-determination theory (Reeve, Deci, & Ryan, 2004; Ryan & Deci, 2000).

Although control beliefs have had a prominent place in formulations of motivation (see Pintrich, 2003), there is no single control theory. Rather, control theories have provided an integrative framework for examining the overall motivational influence of a number of distinct constructs. As discussed by Weisz and Stipek (1982) and Skinner (1996), perceptions of control result from beliefs that behaviors and outcomes are contingently connected and that one possesses the competency or agency to successfully carry out those behaviors.

Competency or agent-means beliefs have been primarily studied as self-efficacy (Bandura, 1997, 2001; Pajares, 1996; Schunk & Pajares, 2004), although other similar competency formulations have appeared in the control literature (see Skinner, 1996, for a comprehensive review). Two types of contingency beliefs have been widely studied. Response–outcome contingencies, reflecting the perceived association between successful or unsuccessful actions and the attainment of outcomes or goals, have been studied as specific outcome expectancies for individual behaviors or domains (Bandura, 1997, 2001; Shell, Colvin, & Bruning, 1995; Shell, Murphy, & Bruning, 1989) and as locus of control, representing the generalized expectancy that outcomes are (internal) or are not (external) contingent on personal action (Chapman, Skinner, & Baltes, 1990; Heckhausen & Schulz, 1995; Rotter, 1966; Skinner, Chapman, & Baltes, 1988; Stipek & Weisz, 1981). Means–ends contingencies (Chapman et al., 1990; Heckhausen & Schulz, 1995; Skinner et al., 1988), reflecting perceived relations

between possible causal influences and the production of successful or unsuccessful action, have been studied primarily within the causal attribution field (Weiner, 1986, 2004). Skinner and her colleagues (Chapman et al., 1990; Skinner, 1996; Skinner et al., 1988) have proposed an additional aspect of control consisting of agent–ends relations that reflect general feelings of control, which are evidenced by expectancy of success (see also Wigfield & Eccles, 2002).

### Control as a Multivariate Multidimensional Construct

Each of the constituent beliefs involved in producing perceptions of control has its own independent motivational influence. Studies have found that self-efficacy (Bandura, 1997, 2001; Pajares, 1996; Schunk & Pajares, 2004), outcome expectancies (Stipek & Weisz, 1981; Shell et al., 1995, 1989; Wigfield & Eccles, 2002), causal attributions (Weiner, 1986, 2004), and success expectancy (Wigfield & Eccles, 2002) all influence effort, choice, strategy use, self-regulation, and achievement in academic domains (see Pajares, 1996; Pintrich, 2003; Stipek & Weisz, 1981; and Wigfield & Eccles, 2002, for reviews). Control formulations, however, have sought to provide a framework for analyzing how these components interact to produce feelings of control. In control theories, control is a multivariate construct in which the whole is greater than the sum of its parts. Feelings of control arise from the overall pattern of agent–means relations (self-efficacy), response–outcome contingencies (outcome expectancies), means–ends contingencies (causal attributions), and agent–ends relations (expectancy of success) rather than from the level of any specific constituent control belief.

Because control is evidenced by the joint, simultaneous effects of the component control beliefs, control could potentially be a higher level, superordinate latent psychological construct that exists in addition to the specific component beliefs. As persons have beliefs about self-efficacy, outcome expectancy, and causal attributions, they might possess a cognitive belief that represents control. This interpretation, however, does not appear to be supported empirically. Factor analyses of component control beliefs (self-efficacy, outcome expectancies, causal attributions, and expectancy of success) have found that these are not reducible to a single latent dimension (Shell & Husman, 2001; Skinner, 1996; Skinner et al., 1988). Factor structures basically confirm that the component beliefs are distinct from one another, with each typically forming its own factorial dimension. As a result, current formulations view control as psychologically multidimensional (e.g., Chapman et al., 1990; Ford & Thompson, 1985; Heckhausen & Schulz, 1995; Skinner, 1996; Skinner et al., 1988; Walls & Little, 2005; Weisz & Stipek, 1982).

Because control does not appear to be a distinct psychological latent construct, feelings of control likely emerge during the course of thought and activity. Control formulations (e.g., Skinner, 1996; Walls & Little, 2005) view persons as active, self-regulating, goal-directed organisms. Feelings of control are intertwined with this active self-regulation. In school, elementary students' current and future control perceptions have been found to vary daily across assignments and in response to grades (Schmitz & Skinner, 1993). Shell et al. (1995, 1989) identified a canonical dimension linking an emergent pattern of control beliefs to reading and writing achievement. These findings suggest that patterns of control that

do not exist within control beliefs themselves can be found within the relations between control beliefs and other variables.

Weisz and Stipek (1982) argued that competency beliefs, consisting of self-efficacy and expectancy of success, and contingency beliefs, consisting of outcome expectancies, locus of control, and causal attributions, had different motivational consequences (see similar arguments by Bandura, 1997, about self-efficacy and outcome expectancy) and hence would be related differently to other variables. Shell and Husman (2001) found empirical support for competency and contingency dimensions of control in canonical correlations examining the relations between control beliefs and academic outcomes. They found separate canonical dimensions associating competency beliefs (self-efficacy) with grades and contingency beliefs (causal attributions and locus of control) with study time and effort. They also found that the dimensions of control in the canonical correlations could not be replicated by factor analysis of the control beliefs themselves. These findings suggest that there are multiple dimensions of control distinct from the multiple factorial dimensions of the component control beliefs.

### The Present Study

Our goal in this study was to further clarify the multidimensional nature of control as expressed in the relationships between control and academic effort, strategy use, and self-regulation. Although in recent theoretical work researchers have expressed a need for systematic, multidimensional characterizations of control within the broader context of motivation (Little, 1998; Skinner, 1996; Skinner et al., 1988), Walls and Little (2005) have noted a lack of empirical studies addressing linkages between control and other motivational constructs. Our first objective was to address this lack of empirical research by examining control beliefs in conjunction with a broader set of motivational constructs.

### Motivational Constructs

*Goal orientation.* Control formulations (e.g., Skinner, 1996; Walls & Little, 2005) hold that control is expressed in the context of goal-directed behavior. Therefore, the exercise of control is affected by a persons' goal orientation. Contemporary achievement goal theory (e.g., Pintrich, 2000a, 2000b) has focused on a distinction between goal orientations for mastery or learning and those for performance. Considerable research has linked these different goal orientations to specific control beliefs. Mastery goal orientation has been linked to more positive self-efficacy and task values, with these all associated with higher levels of strategic self-regulation (e.g., Wolters & Yu, 1996). Self-efficacy beliefs also have been linked to differing self-regulatory consequences of performance approach goal orientation (e.g., Midgley, Kaplan, & Middleton, 2001). Recent research has begun to link dysfunctional self-regulatory strategies, such as self-handicapping and defensive pessimism, to both performance (positive) and mastery (negative) goal orientations in conjunction with external attribution for success, ability attribution for failure, and uncertain control (Martin, Marsh, & Debus, 2003). This previous research strongly suggested that control beliefs and goal orientation are highly interconnected in their influences on students' achievement and self-regulation.

In this study, our objective was to move beyond looking at individual control beliefs and examine how dimensions of control,

such as competency and contingency, which have been found in the relations between control and aspects of self-regulation and achievement (e.g., Shell & Husman, 2001), are linked to students' goal orientation. The constellation of self-efficacy, causal attributions, and outcome expectancies supported by mastery goal orientation may be different than that supported by performance goal orientation. We were also interested in expanding the examination of goal orientation to include work avoidance goal orientation (Ames, 1992; Wolters, 2003), because the control implications of work avoidance goal orientation have not been studied.

*Future time perspective (FTP).* Formulations of control beliefs have long contained references to the link between control and the future. Weiner (1986, 2004) noted that the degree to which causal attributions are seen as continuing into the future plays a major role in their motivational force. Bandura (2001) emphasized that cognitive belief systems exist to allow for forethought and extension of thinking into the future. Control theorists (Skinner, 1996; Schmitz & Skinner, 1993) have presumed that control beliefs influence interpretations of current achievement that subsequently affect future control beliefs and performance.

A person's conceptualization of the future and connection to that future have been referred to as *future time perspective* (FTP; Husman & Lens, 1999; Lens, 1987). Two aspects of FTP that have been found to be of particular relevance to academic achievement are defined as follows: (a) value or valence, defined as the disposition to ascribe high value to goals in the future relative to goals in the present, and (b) connectedness, defined as the disposition to anticipate, in the present, the long-term consequences of a potential action (see De Volder & Lens, 1982; Husman, Derryberry, Crowson, & Lomax 2004; Husman & Lens, 1999; Shell & Husman, 2001). Shell and Husman (2001) found that these FTP constructs were jointly related, with control beliefs, to achievement and studying, with higher connectedness and valence supporting both competency and contingency control dimensions. Miller, Greene, Montalvo, Ravindran, and Nichols (1996) also have found that FTP interacted with goals and perceived ability to predict academic engagement.

These studies suggest that FTP plays a potential role in supporting the influence of control on self-regulation and achievement. Husman and Lens (1999) have argued that FTP can make distal outcomes more salient in current thought; therefore, we would expect students with higher FTP to gain more motivational influence from expectancies for longer range outcomes, potentially increasing the motivational force of outcome expectancies. We also would expect students with higher FTP to have more motivation from attribution to causes that have future stability. To continue the examination of these linkages between control and FTP, we included FTP measures for valence and connectedness in the study.

*Affect.* Feelings of control are thought to produce positive affective responses (e.g., Pekrun, Goetz, Titz, & Perry, 2002; Reeve et al., 2004). Weiner (1986, 2004) has emphasized the different positive and negative affective reactions that result from different attributional patterns. Self-worth theory (Covington, 2004) has also addressed the affective components that underlie why students act and attribute causality in ways that protect positive feelings of worth. Low self-efficacy has been linked to test anxiety (Pajares, 1996).

In the control-value theory of achievement emotion, Pekrun (Pekrun et al., 2006, 2002) has proposed that emotional appraisals are predominantly influenced by control, specifically competence or self-efficacy perceptions, causal attributions, and subjective value, or what are defined here as outcome expectancies. Feelings of control produce positive emotional reactions, whereas feelings of a lack of control produce negative emotional reactions. In addition, Pekrun et al. (2006) have linked control and emotions to goal orientations, arguing that mastery and performance goal orientations influence control perceptions and subsequent emotions. Although Pekrun et al. empirically confirmed predictions for goal-emotion relationships, they did not include explicit measures of control.

Following Pekrun's logic (Pekrun et al., 2006, 2002), we wanted to extend the examination of how emotion, control, and goals affect strategic self-regulation in classrooms. We expected that emotions would be significant components of any control dimensions in ways predicted by Pekrun.

### *Differential Control Beliefs for Different Academic Outcomes*

Most control research has used general measures of academic control (e.g., the Control, Agency, and Means-Ends Interview; Skinner et al., 1988). These measures assume that students have the same control beliefs across all academic outcomes. However, students' beliefs about response-outcome contingencies (outcome expectancies), means-ends contingencies (causal attributions), agent-means competency (self-efficacy), and agent-ends relations (expectancy of success) might be different for learning course material versus achieving an outcome such as high grades. Distinctions between more intrinsic outcomes resulting from learning and extrinsic outcomes resulting from rewards or attaining external criteria are central to many motivational theories, such as self-determination theory (Reeve et al., 2004; Ryan & Deci, 2000), but have not been extensively examined in the control literature.

A second objective, therefore, was to examine whether students had different control beliefs for learning versus achievement outcomes. We assessed causal attributions and outcome expectancies separately for learning course material and obtaining a high grade. For agent-means and agent-ends relations, we assessed both self-efficacy for executing effective strategies for learning course material and expectancy for achieving a high grade.

Because control is expressed within the context of goal orientation (e.g., Skinner, 1996; Walls & Little, 2005), we expected that any differences between students' control beliefs for learning versus achievement outcomes would be expressed in conjunction with differential goal orientation. We expected that patterns of control beliefs for learning would be more strongly linked to mastery goal orientation and that those for achievement would be more strongly linked to performance approach goal orientation.

### *Strategic, Self-Regulatory Variables*

A final objective was to examine control within a broader self-regulatory context than has been previously studied. Shell and Husman (2001) found that competency and contingency beliefs were differentially associated with achievement and studying. They noted that the association they found between competency

and achievement was likely mediated by student learning strategies; however, Shell and Husman did not have measures of cognitive or self-regulatory strategies in their study. Also, Shell and Husman speculated that contingency control beliefs perhaps motivated more general levels of effort and persistence rather than specific strategy use. To examine these questions, we used a more comprehensive array of self-regulation, strategy, and effort measures.

We have included strategic self-regulatory constructs reflecting two somewhat different theoretical and research traditions. The first tradition comes from information processing or, more recently, self-regulation theory (see discussion in Pintrich, 2004). Evolving from early work on study strategies (Weinstein & Mayer, 1986) and metacognition (Brown, Bransford, Ferrara, & Campione, 1983), research in these areas has led to a model of strategic and self-regulated learning that Pressley, Borkowski, and Schneider (1987) have termed *the good strategy user*. Good strategy users are metacognitively active through planning, monitoring, and evaluating their learning and strategy use. They also use a variety of strategies to help them understand, remember, and organize the information they are learning (Pressley et al., 1987; Weinstein, Husman, & Dierking, 2000; Weinstein & Mayer, 1986; Zimmerman & Martinez-Pons, 1988; Zimmerman & Schunk, 2001).

The second tradition has evolved within the more constructivist, knowledge-building approach to learning proposed by Bereiter and Scardamalia (1989; Chan, Burtis, & Bereiter, 1997). Central to the knowledge-building approach is the idea that meaningful learning involves the production of knowledge rather than the reproduction of knowledge. This knowledge building is accomplished by an in-depth study of a topic that goes beyond simple factual or recall learning and is supported by active engagement in classrooms as evidenced by question asking (Scardamalia & Bereiter, 1992).

In addition, because research has begun to examine more dysfunctional self-regulatory strategies (e.g., Martin et al., 2003; Wolters, 2003), we also incorporated assessment of negative strategies similar to the lack of regulation identified by Vermunt and Vermetten (2004; see also Dweck & Leggett, 1988; Zimmerman & Martinez-Pons, 1988). By examining a broad range of potential strategic self-regulatory behaviors, we hoped to better capture the extent and complexity of the relations between control, academic effort, strategy use, and self-regulation.

### Research Questions

Specific research questions for the study were as follows:

1. Are there different dimensions of control associated with different patterns of strategic self-regulation? Specifically, we hypothesized that competency and contingency beliefs would form distinct control dimensions that are associated with different patterns of strategic self-regulation.
2. Are different dimensions of control connected to different goal orientations? Specifically, we hypothesized that control beliefs would form unique dimensions differentiated by mastery, performance approach, and work avoidance goal orientations.
3. How do control beliefs for learning versus achievement outcomes differ in their influence on strategic self-regulation, and are these differences connected to mastery and performance approach goal orientations? Specifically, we hypothesized that control beliefs for learning and grades would be more strongly con-

nected to mastery and performance approach goal orientations, respectively.

4. How are dimensions of control beliefs connected to FTP? Specifically, we hypothesized that higher perceived control would be connected to higher FTP.

5. How are dimensions of control connected to different patterns of affect? Consistent with Pekrun et al. (2006), we hypothesized that higher perceived control would be connected to more positive affect and lower anxiety.

## Method

### Participants

Participants were 397 undergraduates (150 men, 242 women, 5 unknown) at a large Southwestern university who volunteered to participate after being recruited from multiple sections of two upper division educational psychology courses. Participants received course research participation credit for their participation in the study. Students who did not wish to participate in the research were offered the opportunity to complete an alternative assignment for credit.

### Control and Motivation Measures

With the exception of the locus-of-control and FTP measures, all instruments asked students about beliefs concerning the specific class from which they were recruited.

**Self-efficacy.** Self-efficacy for self-regulation and use of learning strategies in the class was assessed by asking participants to rate on a scale of 0 (*no chance*) to 100 (*complete certainty*) their confidence in successfully doing a series of 22 self-regulatory and study strategies (e.g., "Take effective notes over course lectures," "Manage time well enough to have ample study time for the class," "Study effectively for the course exams"). Principal components analysis of the items verified that the items formed a single factor. The self-efficacy score was computed as the mean score of the scale items. Item and reliability analysis indicated acceptable scale properties, with item-total correlations ranging from .46 to .78 and Coefficient  $\alpha = .94$ .

**Expectancy for success.** Expectancy for success (e.g., Wigfield & Eccles, 2002) was assessed by asking participants to rate on a scale of 0 (*no chance*) to 100 (*complete certainty*) their confidence in achieving a grade of A in the course. This type of measure is similar to measures of self-efficacy for grades (e.g., Zimmerman & Bandura, 1994).

**Causal attributions.** Attributions were assessed by asking participants to rate on a 4-point Likert scale from 1 (*very unimportant*) to 4 (*very important*) how important they believed each of 10 possible causes was for producing success and failure in the class from which they were recruited. Attributions were assessed for both an achievement outcome (achieving a high grade) and a learning outcome (learning the course material). Separate principal components analyses of the items for success and failure indicated no differences in the attribution factor structures, so these were combined and factored as a single set. Separate principal components analyses of grade and learning attributions also found no differences in factor structure. However, because grade and learn-

ing attributions still might have different relations with strategic self-regulatory variables, these were retained as separate scales.

For both scales, five factors were identified: (a) strategic learning/effort, consisting of attributions to normal effort, extra effort, and good study skills; (b) ability, consisting of attributions to intelligence and prior knowledge; (c) affect, consisting of attributions to interest and enjoyment; (d) external causes, consisting of attributions to luck and task difficulty; and (e) help, consisting of attributions to obtaining help from friends or teachers. Although these factors do not exactly correspond to Weiner's (1986, 2004) three proposed dimensions of control, they are consistent with those found in previous studies (e.g., Hamilton & Akhter, 2002; Vispoel & Austin, 1995; Weiner, 1986), although luck and task difficulty sometimes form individual factors and sometimes, as we found, combine into a more global external factor.

Scale scores for each of the five factors were produced by taking the mean of the items in each factor. Item and reliability analysis indicated acceptable scale properties for each attribution scale. Item-scale correlations for all but four items with their respective scales were above .40, with the remaining four items between .30 and .37. Coefficient alpha reliability estimates for the grade attribution scales were strategic learning/effort = .78, ability = .69, interest/enjoyment = .81, external causes = .65, and help = .77. Coefficient alpha reliability estimates for the learning attribution scales were strategic learning/effort = .80, ability = .68, interest/enjoyment = .82, external causes = .74, and help = .81.

**Outcome expectancy.** Outcome expectancy was measured by two scales adapted for the classroom situation from the scales used by Shell et al. (1989). The first instrument assessed outcome expectancies for an achievement outcome. Students were asked to rate the importance of having a high grade in their class for successfully achieving 15 life goals drawn from the domains of employment, social activities, family life, education, and general citizenship. The second instrument assessed outcome expectancies for a learning outcome. Students were asked to rate the importance of learning the class content for achieving the same 15 life goals. Both instruments were answered on a 4-point, Likert-type scale ranging from 1 (*very unimportant*) to 4 (*very important*). Scale scores were computed as the mean score of the scale items. Item and reliability analysis indicated acceptable scale properties, with item-scale correlations ranging from .34 to .69 for the grade expectancy scale and .34 to .67 for the learning expectancy scale. Coefficient alpha estimates for the grade expectancy and learning expectancy scales were .89 and .88, respectively.

**Locus of control.** Locus of control was measured using the Rotter Internal-External Locus of Control Scale (Rotter, 1966). The instrument is a 29-item questionnaire with 23 assessment items and 6 filler items. Each assessment item offered a choice between an internal response and an external response, and participants were asked to indicate which of the two choices they most strongly believed to be true. The instrument is commonly scored in the external direction; however, to make the direction of the scores consistent with the scales for causal attribution measures of internality and externality, the scoring was done by summing the internal responses so that higher scores indicated a more internal locus of control.

**Goal orientation.** Students' personal goal orientations for the class were measured using a scale based on Dweck's formulation (e.g., Dweck & Leggett, 1988) adapted from Schraw, Horn,

Thorndike-Christ, and Bruning (1995). In response to the following stem: "Students differ in what they want to get out of the courses they take. Use the scale given to rate how important achieving each of the following is for you," students rated how important achieving each goal was in the class on a 4-point Likert scale ranging from 1 (*very unimportant*) to 4 (*very important*).

Five items reflected mastery or learning goal orientation: (a) "Learning new knowledge or skills in the class just for the sake of learning them," (b) "Really understanding the course material," (c) "Being challenged by course assignments," (d) "Feeling satisfied that you got what you wanted from the course," and (e) "Knowing more than you did previously about the course topics." Five items reflected performance approach goal orientation (e.g., Wolters, 2003): (a) "Doing better than the other students in the class on tests and assignments," (b) "Proving to other people that you are a good student," (c) "Remembering enough from the class to impress other people," (d) "Getting the highest grade in the class," and (e) "Impressing the instructor with your performance."

Because the course from which most students were recruited was a highly popular elective class in which achievement was not directly related to students' majors, we did not feel that performance avoidance goal orientation (Pintrich, 2000a, 2000b) was likely to be very applicable. However, because the course was often taken because it was seen as "easy," we did feel that goals reflecting work avoidance orientation (Ames, 1992; Wolters, 2003) might be applicable. Therefore, we added three items reflecting work avoidance goal orientation: (a) "Not having to work too hard in the class," (b) "Getting a passing grade with as little studying as possible," and (c) "Getting through the course with the least amount of time and effort."

A principal components analysis verified the three distinct goal orientation scales. Item and reliability analysis indicated acceptable scale properties, with item-scale correlations ranging from .37 to .58 for the learning goal orientation scale, from .42 to .64 for the performance approach goal orientation scale, and from .73 to .87 for the work avoidance goal orientation scale. Coefficient alpha estimates for the learning, performance approach, and work avoidance goal orientation scales were .72, .79, and .78, respectively. Scale scores were computed as the mean of the items in each goal orientation scale.

**FTP.** FTP was measured with the Future Time Perspective (FTP) Scale (Shell & Husman, 2001). The FTP Scale is a 25-item instrument containing two subscales: Connectedness and Valence. The FTP Connectedness scale consists of 16 questions that assess the contingent or instrumental relationship between current behavior and future goal attainment. The FTP Valence scale consists of 9 questions that assess the relative importance of attaining immediate versus long-range future outcomes. Participants are asked to indicate their agreement with each question using a 5-point Likert scale ranging from 1 (*strongly disagree*) to 5 (*strongly agree*). Scale scores are computed as the mean of the items in each scale. The complete scale with instrument validation psychometrics can be found in Shell and Husman (2001). For the sample in the present study, the coefficient alpha reliability estimates for the FTP Connectedness and Valence subscales were .86 and .83, respectively.

**Course affect.** Affect was measured by the Positive and Negative Affect Scale (Watson, Clark, & Tellegen, 1988), a 22-item scale that asks students to rate the frequency with which they

experience 22 emotions (11 positive and 11 negative) in their class on a 5-point scale ranging from 1 (*a few times or none*) to 5 (*most of the time, 80%–100% of the time*). Positive emotions are interested, excited, attentive, active, enthusiastic, proud, alert, capable, in control, inspired, and determined. Negative emotions are scared, out of control, irritable, ashamed, nervous, distressed, upset, guilty, hostile, frustrated, and afraid. A principal components analysis verified the existence of separate positive and negative scales. Item and reliability analysis indicated acceptable scale properties, with item–scale correlations ranging from .38 to .76 for the Positive Affect scale and from .49 to .72 for the Negative Affect scale. Coefficient alpha estimates for the Positive and Negative Affect scales were .88 and .88, respectively. Scale scores were computed as the mean of the items in each scale.

**Course anxiety.** The course anxiety scale was developed as an extension of test anxiety measures in instruments such as the Motivated Strategies for Learning Questionnaire (MSLQ; Pintrich, Smith, Garcia, & McKeachie, 1993). Assessment of anxiety was extended from testing situations to a broader set of 15 class-related situations (e.g., “When I take tests, I think about the consequences of failing”; “When I’m in class, I worry about being called on and not knowing the answer”; “I fear having to do tests, papers, and other graded assignments”; “When I do assignments, I worry about how well I will do”; “When I take a test, I get so worried that my mind just goes blank”). Students were asked to rate the frequency on a 5-point Likert-type scale ranging from 1 (*almost never*) to 5 (*almost always*) that they felt concern, anxiety, or worry about each of the 15 situations. Principal components analysis of the items verified that the items formed a single factor. Item and reliability analysis indicated acceptable scale properties, with item–total correlations ranging from .33 to .71 and coefficient  $\alpha = .90$ . Scale scores were computed as the mean of the 15 items.

### Strategic Self-Regulatory Measures

Strategic self-regulation was assessed with the Student Perceptions of Classroom Knowledge-Building Scale (SPOCK; Shell et al., 2005). The SPOCK was developed to extend the assessment of student self-regulated, strategic learning beyond current measures such as the MSLQ (Pintrich et al., 1993) and the Learning and Study Strategies Inventory (LASSI; Weinstein, Zimmermann, & Palmer, 1988) by including strategies, question asking, and behaviors based on the knowledge-building, question-asking, and intentional learning models of Bereiter and Scardamalia (1989; Chan et al., 1997) and negative aspects of student regulation as portrayed in descriptions of learned helplessness (e.g., Dweck & Leggett, 1988) and in the lack-of-regulation strategy of Vermunt and Vermetten (2004). The SPOCK also contains scales that were not used in this study that assess students’ perceptions of collaboration and teacher directedness in the classroom.

The instrument asks students about strategic self-regulatory behavior within a specific course. Students were asked to respond only for the class from which they were recruited. All questions were answered on a 5-point Likert scale. Scale points were described as 1 (*almost never—occurs on a very rare occasion or not at all*), 2 (*seldom—does not occur often; occurs about one quarter of the time*), 3 (*sometimes—occurs about half of the time*), 4 (*often—occurs frequently; occurs about three quarters of the time*), and 5 (*almost always—usually or always occurs; on a rare*

*occasion it may not occur*). The SPOCK measures four aspects of students’ perceptions of their own strategic self-regulation: self-regulated strategy use, knowledge building, question asking (both high level and low level), and lack of regulation.

The Self-Regulated Strategy Use scale (8 items) assesses the extent of student planning, goal setting, monitoring, and evaluation of studying and learning: (a) “In this class, I try to determine the best approach for studying each assignment”; (b) “In this class, I try to monitor my progress when I study”; (c) “In this class, I make plans for how I will study”; (d) “In this class, I use different ways to organize my thoughts, such as diagrams, charts, timetables, etc.”; (e) “In this class, I check myself to see how well I am understanding what I am studying”; (f) “In this class, I take notes and jot down questions when I am reading the class materials”; (g) “In this class, I focus on understanding the important ideas in what I am reading or studying”; and (h) “In this class, I set goals for myself which I try to accomplish.” These items assess strategic behaviors and study strategies typically associated with models of strategic self-regulation (e.g., Pintrich, 2004; Weinstein & Mayer, 1986) and what Pressley et al. (1987) have termed the good strategy user.

The Knowledge-Building scale (8 items) assesses the extent of student exploration and interconnection of knowledge from the class on the basis of the knowledge-building and intentional learning models of Bereiter and Scardamalia (1989; Chan et al., 1997). Questions in this scale focus on going beyond the given material and on tying the information being learned to other courses and existing knowledge: (a) “Whenever I learn something new in this class, I try to tie it to other facts and ideas that I already know”; (b) “As I study the topics in this class, I try to think about how they relate to the topics I am studying in other classes”; (c) “In this class, I set goals based on things I really want to learn”; (d) “In this class, I ask questions that allow me to explore topics that interest me”; (e) “As I study topics in other classes, I try to think about how they relate to the topics I am studying in this class”; (f) “In this class, I do assignments primarily to learn something new”; (g) “In this class, I ask questions that can only be answered by exploring new information”; and (h) “As I study a topic in this class, I try to consider how the topic relates to other things I know about.”

Two scales assess the extent of question asking in class (see Scardamalia & Bereiter, 1992). The High-Level Question-Asking scale (4 items) assesses the extent to which students ask questions that extend or expand on the basic information being provided in the class: (a) “In this class, I ask questions in order to help me learn new things”; (b) “In this class, I ask questions about things I am curious about”; (c) “In this class, I ask questions to help me know more about the topics we are covering in class”; and (d) “In this class, I ask questions to help me better understand the things I am trying to learn.” The Low-Level Question-Asking scale (4 items) assesses the extent to which students ask questions to obtain or clarify basic course information: (a) “In this class, I ask questions so that I can be sure I know the right answers for tests”; (b) “In this class, I ask questions to be clear about what the instructor wants me to learn”; (c) “In this class, I ask questions to help me prepare for tests”; and (d) “In this class, I ask questions so that I can find out what information the instructor thinks is important.”

The Lack-of-Regulation scale (4 items) assesses students’ lack of understanding of how to study and need for assistance and guidance in studying: (a) “In this class, when I get stuck or

confused about my schoolwork, I need someone else to figure out what I need to do"; (b) "In this class, I have trouble figuring out how to approach studying"; (c) "In this class, I rely on the instructor to tell me what to do"; and (d) "In this class, when I don't know an answer to a question, I try to hide the fact that I don't know." This scale assessed behaviors similar to those in the lack-of-regulation orientation identified by Vermunt and Vermetten (2004).

Scale scores were computed as the mean score of the scale items. Coefficient alpha reliability estimates for the Self-Regulated Strategy, Knowledge-Building, High-Level Question-Asking, Low-Level Question-Asking, and Lack-of-Regulation scales were .81, .84, .92, .91, and .48, respectively.<sup>1</sup> With the exception of lack of regulation, these reliability estimates for the SPOCK are consistent with those obtained for similar instruments, such as the MSLQ (Pintrich et al., 1993), the LASSI (Weinstein et al., 1988), and the Study Process Questionnaire (Biggs, Kember, & Leung, 2001).

Hamman (1998) found that SPOCK scores for the Self-Regulated Strategies, Knowledge-Building, and Lack-of-Regulation scales were correlated in expected ways with scores on comparable subscales of the LASSI (Weinstein et al., 1988). Shell et al. (2005) found that SPOCK scores, especially Lack-of-Regulation scale scores, predicted high school students' course grades.

In addition to the SPOCK, two measures of studying taken from Shell and Husman (2001) were used. Study time was assessed by asking participants to indicate the average number of hours per week they spent studying for the class from which they were recruited on a scale ranging from 1 to 7 representing 5-hr units from 1 (*less than 5 hours per week*) to 7 (*over 30 hours per week*). Perceived study effort was assessed by asking participants to indicate their perceptions of the effort they put forth studying for the class from which they were recruited relative to most other students in the class on a 5-point Likert scale with the following point designations: 1 (*I put forth much less effort studying*), 2 (*I put forth somewhat less effort studying*), 3 (*I put forth about the same effort studying*), 4 (*I put forth somewhat more effort studying*), and 5 (*I put forth much more effort studying*).

### Procedures

Data were collected over two semesters. In both semesters, participants in groups of 10 to 20 completed the measures in a single session proctored by one of the researchers or a graduate research assistant. In one semester, measures were administered in two packets, with students answering on Scantron mark sense sheets for one packet and on the packet itself for the other packet. In the other semester, measures were administered in two packets, with students answering on Scantron mark sense sheets but answering self-efficacy questions on their own form. Demographic questions about gender, age, and year in school were included in the packets used in both semesters.

### Data Analysis

We conducted canonical correlation analyses using the canonical correlation macro in SPSS for Windows Version 13.0. The strategic self-regulatory variable set consisted of SPOCK scores

along with study time and perceived study effort. The control and motivation variable set consisted of self-efficacy, expectancy for success, causal attribution, outcome expectancy, locus of control, goal orientation, FTP, course affect, and course anxiety variables.

## Results

### Descriptive Statistics

The means, standard deviations, and zero-order correlations between all variables are provided in Table 1. The average profile of students' control, motivation, and strategic self-regulation as portrayed in the mean scores fit the good strategy user described by Pressley et al. (1987; see also Weinstein et al., 2000; Zimmerman & Schunk, 2001), which would be expected of primarily junior and senior students taking an upper level course. Students reported about average levels of self-regulated strategy use, somewhat infrequent knowledge building, and infrequent question asking and lack of regulation. They reported studying for the course about 5–10 hr per week with somewhat of a below-average effort. These levels of studying and self-regulated strategic behavior seem consistent with what would be expected for students in a general elective course. Students expressed generally high levels of self-efficacy for using learning strategies and high expectancy for grades. They attributed success and failure most to effort/strategy use and affect (interest and enjoyment) for both learning and grades. Students had moderate levels of outcome expectancy for both learning and grades and neither a strong internal nor a strong external locus of control. These control patterns are consistent with typical patterns found among college and even younger student populations (e.g., Skinner, 1996). Students expressed higher mastery goal orientation than either performance approach or work avoidance orientation, which were similar to each other. They had high FTP connectedness and middle-range FTP valence, suggesting a generally high overall FTP. They expressed generally high positive affect for the class and lower levels of negative affect and anxiety.

### Canonical Correlation Results

We first present the results of the canonical correlation analysis. We then address each of our research questions. Results of the

<sup>1</sup> The coefficient alpha estimate for lack of regulation is consistent with those found for the same four-item scale in two high school samples (.54 and .50) by Shell et al. (2005). Coefficient alpha represents the minimum possible scale reliability. True reliability cannot be lower but may be higher. Two scale conditions can depress alpha relative to true reliability (see Thorndike, 1997). The first is skewed item responses. Because few college students perform the behaviors assessed in the Lack-of-Regulation scale, item scores for three of the four items were heavily skewed, with 60%–80% of students answering 1 or 2 on the 5-point scale. The second is Spearman-Brown suppression. Coefficient alpha can underestimate reliability in short scales, especially if skewed items are present. A revised version of the SPOCK with a longer seven-item Lack-of-Regulation scale had an alpha of .63 with a high school sample (Shell et al., 2005) and .64 with a college sample (Shell, 2005). These later estimates suggest that for the current sample the coefficient alpha estimate is experiencing Spearman-Brown suppression, and true scale reliability is likely closer to the .64 attained with the longer scale.

canonical correlation analysis are shown in Table 2. For each variable set, a canonical variate, which is a latent linear combination of the variables, similar to a factor in factor analysis, is created. The canonical correlation is the correlation between these canonical variates for the two variable sets. Of the seven possible canonical correlations (equal to the number of variables in the smallest set), five were statistically significant on the basis of sequential chi-square testing (see Stevens, 2002; Thompson, 1984). Examination of explained variance in the correlation ( $R_c^2$ ) and redundancy analysis, however, suggested that only the first three correlations were meaningful. Each of the first three correlations exceeded .50, with the set of control and motivation variables accounting for 28% to 45% of the variance in strategic self-regulatory variables. These results indicated meaningful prediction of strategic self-regulation from the control and motivation variables. No other canonical correlation was higher than .38. Analysis of redundancy variance found that the variates for the first three canonical correlations combined explained 61% of the variance in the strategic and self-regulatory variables. Variates for the remaining two significant correlations explained only 20% of the variance in the strategic and self-regulatory variables.

For each variable set, the canonical variate describes a latent dimension. This latent dimension portrays the combined influence of the variables in the set. Identifying what the latent dimension represents is done by interpreting which variables in the set are making meaningful contributions to the variate. Contribution is determined from two indicators: canonical coefficients and structure coefficients. The canonical coefficients are the weighting of each variable in the canonical discriminant function that defines the variate. They reflect the independent contributions of each variable to the variate with the other variables in the set partialled out, similar to beta weights in a regression equation. The structure coefficients (or loadings) are the correlation between participants' scores on an original variable and their canonical variate scores (scores produced by multiplying the scores for each variable by their respective canonical coefficients). They are the same as factor loadings in a factor analysis. If variables in the set are intercorrelated, the pattern of canonical coefficient weights can be arbitrary. Because of this, the structure coefficients are usually preferred for interpreting which variables are contributing to a canonical variate. However, the structure coefficients may not reflect all of the contributions if the variables are not highly intercorrelated. Also, if variables that are themselves intercorrelated have independent contributions to the canonical variate in opposite directions (one

positive and one negative), neither may be correlated very highly with the resulting linear combination (see Shell & Husman, 2001; Stevens, 2002; or Thompson, 1984, for more complete discussions of interpreting contributions to canonical variates). In general, we based our decisions on the structure coefficients. We considered a structure coefficient above .30 to indicate meaningful contributions. However, if a variable had a high canonical coefficient relative to other variables, we also considered it to be a contributor to the variate, even if its structure coefficient was less than .30. The canonical coefficients and structure coefficients for each of the three canonical correlations are provided in Table 3.

The canonical and structure coefficients can identify which variables make a contribution to the canonical variates. Like a factor in factor analysis, however, the identified pattern of variable contribution is meaningful only in the context of the theory and literature of the specific constructs and behaviors being examined. Also, the canonical variates for each correlation define a dimensional continuum that can be unipolar or bipolar. In a unipolar dimension, movement along the continuum indicates change from low to high in a unitary entity, such as an increase in self-efficacy or an increase in math or reading ability. In a bipolar dimension, movement along the continuum indicates a shift in qualitatively distinct states, such as a change from introversion to extroversion. The low end of the dimension can be examined by changing the sign of the canonical and structure coefficients from positive to negative and vice versa. As with the interpretation of the meaning of a canonical variate, decisions about whether a canonical dimension is unipolar or bipolar are based on whether the ends of the continuum define patterns that are theoretically interpretable in relation to the literature for the variables in the dimension.

*Structure of the first canonical dimension.* At the high end of the first canonical dimension, the structure coefficients portrayed a pattern of higher self-regulated strategy use, knowledge building, high- and low-level question asking, study time, and study effort. This pattern of strategic self-regulation was associated with a pattern of structure coefficients portraying higher positive control beliefs (higher self-efficacy, higher causal attributions for both learning and grades to strategy use/effort and help and for grades to ability, and higher outcome expectancy for learning and grades), higher mastery and performance approach goal orientations and lower work avoidance goal orientation, and higher positive affect. The pattern of strategic self-regulation, control, and motivation at the high end of the dimension appears to depict a student who fits the description of the good strategy user (Pressley et al., 1987) or the strategic learner (Weinstein et al., 2000).

At the low end of the dimension, the structure coefficients portrayed a pattern of lower self-regulated strategy use, knowledge building, high- and low-level question asking, study time, and study effort. This pattern of lower active strategic self-regulation was associated with a pattern of structure coefficients portraying low control (lower self-efficacy; lower attribution of causality to strategy use/effort, ability [for grades], and help; and lower outcome expectancy for both grades and learning), higher work avoidance and lower mastery and performance approach goal orientations, and lower positive affect. We might have interpreted this dimension as simply unipolar, reflecting increasing levels of motivated strategic self-regulation, except for the strong contribution of work avoidance

Table 2  
Summary Statistics for Canonical Correlation Analysis

Correlation	$R_c$	$R_c^2$	Wilks's $\Lambda$	$\chi^2$	$df$	$p$	Proportion of variance	
							Set 1	Set 2

Course anxiety	.11	.29	-.15	-.20	.38	.66

Note. Canonical and structure are the standardized canonical coefficients and structure coefficients, respectively.

goal orientation to the low end of the dimension. The higher work avoidance goal orientation suggests a deliberate self-regulatory choice to be strategically inactive and disengaged from the class. Also, this pattern of control, motivation, and strategic self-regulation has been identified in other research, such as that conducted by Reeve et al. (2004), who described the amotivational student as passively "going through the motions" (p. 38), and Moreno, Shell, and Pirritano (2007), who described the apathetic student. We therefore believe that this dimension is bipolar.

*Structure of the second canonical dimension.* At the high end of the second canonical dimension, the structure coefficients portrayed a pattern of higher knowledge-building strategies and lower lack of regulation, but also lower self-regulated strategy use and study time. Canonical coefficients also suggested a contribution from higher high-level and lower low-level question asking. These likely did not have high structure coeffi-

cients because they contributed in opposite directions to the variate, even though they are themselves highly correlated (see Table 1). This pattern of strategic self-regulation was associated with a pattern of structure coefficients portraying higher positive control beliefs (higher self-efficacy and expectancy for success, higher outcome expectancies for learning but not for grades, and lower causal attribution to strategy use/effort), higher mastery goal orientation, and higher positive and lower negative class affect. Canonical coefficients also suggested a contribution to control from higher causal attribution to interest and enjoyment, especially for grades. The high end of this dimension seems to fit the descriptions of the knowledge-building student (Bereiter & Scardamalia, 1989; Chan et al., 1997), the intrinsically motivated, autonomous student described in self-determination theory (Reeve et al., 2004; Ryan & Deci, 2000), or the mastery-oriented student in achievement goal theories (e.g., Pintrich, 2003).

What differentiates these students from those portrayed by Dimension 1 is the lack of general self-regulated strategy use. As these students' knowledge building increased, their self-regulated strategy use and study time decreased. Motivationally, causal attributions to strategic learning/effort, which were strongly associated with Dimension 1, also decreased. Also, outcome expectancy for grades and performance approach goal orientation were absent from Dimension 2. These students appear relatively unconcerned with traditional indicators of success, such as grades or performing well compared to others, even though they expect to get high grades. Also, they do not engage much in the general metacognitive and learning strategies that might be expected to produce higher grades. Rather, they appear to pursue deeper learning for their own growth and development.

At the low end of the dimension, the structure coefficients portrayed a pattern of higher self-regulated strategy use and study time but lower knowledge building and higher lack of regulation. Canonical coefficients also suggested a contribution from higher low-level and lower high-level question asking. This pattern of strategic self-regulation was associated with a pattern of structure coefficients portraying a mixed pattern of control (lower self-efficacy and expectancy for grade success, higher causal attribution to strategic learning/effort, and lower outcome expectancy for learning), lower mastery goal orientation, and lower positive and higher negative class affect. Canonical coefficients suggested a contribution to control from lower causal attribution to interest and enjoyment for both learning and grades.

The second canonical dimension appears to be bipolar, as the low end of the dimension depicts students who fit descriptions of surface learners found in the literature (see Pressley et al., 1987; Weinstein & Mayer, 1986). These students seem to have little personal investment in the class as reflected in the low outcome expectancies for learning and low mastery goal orientation. The students understand that good self-regulated strategy use will lead to success in the course, and they are willing to put in the study time and apply general planning, monitoring, and learning strategies to be successful. However, the students express higher lack of regulation, indicating uncertainty about the effectiveness of their strategy use, likely as a result of their lack of self-efficacy in their ability to effectively apply the strategies they are using and low expectation for high grades. This produces a very rote or surface approach to learning.

*Structure of the third canonical dimension.* At the high end of the third canonical dimension, the structure coefficients portrayed a pattern primarily consisting of higher lack of regulation with some higher knowledge building. The canonical coefficients suggested a contribution from higher low-level and lower high-level question asking as well as lower self-regulated strategy use. This pattern of strategic self-regulation was associated with a pattern of structure coefficients portraying a dysfunctional pattern of control (lower self-efficacy for self-regulation, lower expectancy for grade success, higher outcome expectancy for both learning and grades, and higher causal attribution for both learning and grades to external causes and help), higher work avoidance goal orientation, and higher negative affect and anxiety.

The students portrayed by the high end of this dimension fit descriptions of learned helplessness (Dweck, 1999; Dweck & Leggett, 1988; Stipek & Kowalski, 1989; Weiner, 1986). These students predominantly express lack of regulation, indicating con-

fusion and uncertainty about how to effectively approach studying for the class with corresponding low levels of self-regulated strategy use. When they do ask questions, these students ask low-level questions focused on finding out what the teacher wants and getting rote answers for tests rather than personal meaning-making questions. Their control beliefs are equally dysfunctional. Such students see succeeding in the course and learning the material as important but lack efficacy for executing the strategies and self-regulation need to be successful and hence have little expectation of success. The students attribute causality to external factors, reflecting a lack of personal control over their own success and learning. This lack of control is associated with high negative affect and anxiety. It is probably not surprising that they have only a work avoidance goal orientation.

At the low end of the dimension, the structure coefficients portrayed a pattern of lower lack of regulation and lower knowledge building, with the canonical coefficients showing higher self-regulated strategy use, higher high-level question asking, and lower low-level question asking. This pattern of strategic self-regulation was associated with a pattern of structure coefficients portraying a mixed pattern of control (higher self-efficacy for self-regulation and expectancy for grade success, lower outcome expectancy for both learning and grades, and lower causal attribution for both learning and grades to external causes and help), lower work avoidance goal orientation, and lower levels of negative affect and anxiety.

This pattern of strategic self-regulation, control, and motivation was not theoretically interpretable. This end of the dimension contained aspects of both the strategic learner and the surface learner, but the pattern found did not conform to any strategic or motivational patterns in the existing literature. Therefore, we believe that this dimension is unipolar and reflects only increasing levels of learned helplessness rather than two qualitatively different patterns of self-regulation.

### *Research Question 1: Are There Different Dimensions of Control Associated With Different Patterns of Strategic Self-Regulation?*

Although we found strong support for multiple control and strategic self-regulation dimensions, our hypothesis that competency and contingency beliefs would form distinct control dimensions was not supported. The canonical correlation analysis found three distinct dimensions that contained five patterns of control. Two of these five patterns reflected positive perceived control. The good strategy user end of Dimension 1 conformed to classic formulations of high perceived control (e.g., Chapman et al., 1990; Ford & Thompson, 1985; Heckhausen & Schulz, 1995; Skinner, 1996; Skinner et al., 1988; Walls & Little, 2005; Weisz & Stipek, 1982). This pattern consisted of high self-efficacy for learning strategies, causal attribution to strategy use/effort and help for both grades and learning and to ability for grades, and high outcome expectancy for learning and grades. The only deviation from the expected control pattern was a lack of expectancy for grade success. This pattern of perceived control was associated, as would be expected, with a strategic self-regulatory pattern of high self-regulated strategy use, knowledge building, question asking, study time, and study effort.

The knowledge-building end of Dimension 2, however, identified a second positive perceived control pattern. This pattern consisted of high self-efficacy for learning strategies, high expectancy for grade success, and high outcome expectancy for learning but not grades. There was high causal attribution to internal causes, but to interest and enjoyment rather than to strategy use/effort or ability. In fact, attribution to strategy use/effort contributed negatively. This pattern of control was linked to a more specific strategic self-regulatory pattern of higher knowledge-building strategies and high-level question asking.

Three control patterns were more negative. The pattern of control in the learned helplessness end of Dimension 3 has been noted previously as being particularly dysfunctional and psychologically damaging (e.g., Bandura, 1997; Dweck & Leggett, 1988; Skinner, 1996; Stipek & Kowalski, 1989; Weiner, 1986). This pattern consisted of high outcome expectancy for learning and grades but low self-efficacy and expectancy for grade success along with causal attributions to external causes and help. Students with this pattern of control see the class as important but see themselves as incapable of effectively exerting control and learning. This pattern of control was associated with a strategic self-regulatory pattern of high lack of regulation and low-level question asking and low self-regulated strategy use and high-level question asking. In something of an anomaly, this pattern also contained higher knowledge-building strategies. This may reflect an association between these strategies and the high learning outcome expectancy in the control pattern.

A second pattern of low personal control was evidenced in the apathetic end of Dimension 1. This pattern consisted of low self-efficacy; low outcome expectancies for both learning and grades; and low causal attributions to strategy use/effort, help, and ability. As would be expected in control theory (Skinner, 1996), this almost complete absence of any sense of personal control was associated with a strategic self-regulatory profile of virtually no strategy use, knowledge building, question asking, or studying. Unlike the learned helpless pattern, however, this self-regulatory pattern had no contribution from lack of regulation, suggesting that not doing these self-regulatory behaviors was not due to a lack of understanding what to do.

The final pattern of somewhat mixed control was found in the surface learning end of Dimension 2. This pattern consisted of low self-efficacy, expectancy for grade success, and outcome expectancy for both learning and grades, like the apathetic pattern, but contained high causal attributions to strategy use/effort and help, like the good strategy user pattern. This control pattern was associated with a strategic self-regulatory pattern of higher self-regulated strategy use, low-level question asking, and study time, but also higher lack of regulation and lower knowledge-building strategies and high-level question asking. This control pattern suggests a belief that classroom success depends on one's own strategy use and effort but a lack self-efficacy in one's ability to do these strategies effectively. This is then manifest in higher self-regulated learning strategies and study time, but also in higher lack of regulation, suggesting an uncertainty about how to effectively apply the strategies being attempted.

Although control beliefs did not form unique competency and contingency dimensions, patterns of control consistent with the competency and contingency framework (Shell & Husman, 2001; Weisz & Stipek, 1982) were apparent. Regardless of dimension or

pattern of contingency beliefs, high self-efficacy for learning strategies was always part of a control pattern associated with a strategic self-regulatory pattern that would be expected to produce higher achievement. More specifically, as hypothesized by Shell and Husman (2001), higher self-efficacy was always part of a control pattern associated with a strategic self-regulatory pattern containing higher knowledge-building strategies and high-level question asking. Lower self-efficacy was always part of a control pattern associated with a self-regulatory pattern that would be expected to result in lower achievement. Specifically, lower self-efficacy for learning strategies was always part of a control pattern associated with higher lack of regulation.

Conversely, contingency beliefs were part of control patterns associated with all strategic self-regulatory patterns except the apathetic end of Dimension 1; so, as found by Shell and Husman (2001), they were not differentially associated with self-regulatory patterns likely to produce higher and lower achievement. However, the association of contingency beliefs with reported study time, study effort, and self-regulated strategy use mirrored the associations found by Shell and Husman. In all dimensions, higher attribution to strategy use/effort and higher outcome expectancy were part of a control pattern associated with a strategic self-regulatory pattern containing higher studying and higher use of effortful strategic self-regulatory strategies. These findings strengthen the hypothesis that contingency beliefs motivate effort and general level of strategic behavior, whereas competency or self-efficacy beliefs more specifically motivate the use of more cognitively complex deep processing strategies.

### *Research Question 2: Are Different Dimensions of Control Connected to Different Goal Orientations?*

We found partial support for our hypothesis that control beliefs would form unique dimensions differentiated by mastery, performance approach, and work avoidance goal orientations. Two of the three identified dimensions had contributions from only a single goal orientation. Mastery goal orientation was the only goal orientation contributing to Dimension 2 (knowledge building/surface learning), and work avoidance goal orientation was the only goal orientation contributing to Dimension 3 (learned helplessness). Dimension 1 (good strategy user/apathetic) had contributions from all three goal orientations: mastery, performance approach, and work avoidance.

Regardless of the canonical dimension, mastery goal orientation always contributed to a dimension in conjunction with a pattern of high perceived control, and work avoidance goal orientation always contributed to a dimension in conjunction with a pattern of low or dysfunctional perceived control. Performance approach goal orientation contributed to a dimension in conjunction with a pattern of high perceived control in the good strategy user end of Dimension 1 but did not contribute to the other dimensions. These connections between goal orientation and perceived control generally correspond to what would be expected on the basis of theory and previous research (e.g., Martin et al., 2003; Midgley et al., 2001; Pekrun et al., 2006; Pintrich, 2000a, 2000b; Skinner, 1996; Wolters & Yu, 1996)

*Research Question 3: How Do Control Beliefs for Learning Versus Achievement Outcomes Differ in Their Influence on Strategic Self-Regulation, and Are These Differences Connected to Mastery and Performance Approach Goal Orientations?*

We found few differences in the contributions to the canonical variates for control beliefs for learning and achievement outcomes and no support for our hypothesis that control beliefs for learning and grades would be more strongly connected to mastery and performance approach goal orientations, respectively. The contributions from students' causal attributions for learning and grades paralleled each other in all dimensions. Although there were no differential contributions for learning and grade attributions, causal attributions did contribute differentially to the canonical dimensions in conjunction with different goal orientations. Attributions to effort and strategy use contributed to Dimension 1 (good strategy user/apathetic) in the same direction as the contributions from both mastery and performance approach goal orientations but contributed in the opposite direction to mastery goal orientation in Dimension 2 (knowledge building/surface learning). Apparently, students at the knowledge-building end of Dimension 2 do not see pursuit of mastery-oriented goals and personal knowledge building as being caused by effort and learning strategies, whereas students at the surface learning end of this dimension attribute causality to effort and strategy use and do not pursue mastery-oriented goals. Attribution to help contributed to Dimension 1 (good strategy user/apathetic) in the same direction as mastery and performance approach goal orientations and in the opposite direction to work avoidance goal orientation but contributed to Dimension 3 (learned helplessness) in the same direction as work avoidance goal orientation. External causes, as expected, contributed to Dimension 3 (learned helplessness) in the same direction as work avoidance goal orientation.

Unlike for causal attributions, there were differences in how students' learning and grade outcome expectancies contributed to the dimensions. In Dimension 1 (good strategy user/apathetic) and Dimension 3 (learned helplessness), the contributions from learning and grade outcome expectancies paralleled each other. However, in these dimensions, their contributions did not parallel the contributions from any specific goal orientation, nor were they associated consistently with aspects of strategic self-regulation. In Dimension 1 (good strategy user/apathetic), higher outcome expectancies contributed in the same direction as mastery and performance goal approach goal orientations and in the opposite direction to work avoidance goal orientation and were associated with higher effort and self-regulated strategy use, but in Dimension 3 (learned helplessness), they contributed in the same direction as work avoidance goal orientation and were associated with lower effort and general strategy use. In Dimension 2 (knowledge building/surface learning), only higher learning outcome expectancies contributed to the dimension. This contribution was in the same direction as mastery goal orientation and was associated with knowledge building but not with effort and general strategy use. Overall, outcome expectancies did not appear to be uniquely linked with any specific goal orientation.

Self-efficacy for learning strategies always contributed to a dimension in the same direction as mastery goal orientation, suggesting a strong link between efficacy for learning and being

oriented toward setting learning or mastery goals. In Dimension 1 (good strategy user/apathetic), self-efficacy for learning strategies contributed in the same direction as performance approach goal orientation, but self-efficacy for learning and performance approach goal orientation did not contribute similarly to other dimensions, suggesting a less strong link with self-efficacy than for mastery goal orientation. In Dimension 1 (good strategy user/apathetic) and Dimension 3 (learned helplessness), self-efficacy for learning strategies contributed in the opposite direction as work avoidance goal orientation. Unexpectedly, success expectancy for grades, which reflects belief about an achievement outcome, did not contribute to any dimension with performance approach goal orientation. In Dimension 2 (knowledge building/surface learning), it contributed in the same direction as higher mastery goal orientation, and in Dimension 3 (learned helplessness), it contributed in the same opposite direction as work avoidance goal orientation.

*Research Question 4: How Are Dimensions of Control Beliefs Connected to FTP?*

We found no support for our hypothesis that higher perceived control would be connected to higher FTP. Unlike previous findings (Shell & Husman, 2001), neither FTP valence nor FTP connectedness contributed meaningfully to any of the three canonical dimensions. A key difference between the Shell and Husman (2001) study and the present study, however, is that this study was contextualized within a single class, whereas Shell and Husman examined overall college GPA and general study time and effort for all classes. Theoretically, FTP is a dispositional psychological construct that is decontextual. Thus, the FTP variables examined may not have been as strongly associated with the class-specific strategic, self-regulatory behaviors as the class-specific control, goal orientation, and affective variables were, even if these FTP variables are associated with academic achievement and strategic self-regulation in general. These results suggest that further research is needed to clarify how variables at different levels of decontextualization interact in classroom settings.

*Research Question 5: How Are Dimensions of Control Connected to Different Patterns of Affect?*

Consistent with Pekrun et al. (2006), we found support for our hypothesis that higher perceived control would be connected to more positive affect. A pattern of high perceived control contributed in the same direction as positive class affect in Dimension 1 (good strategy user/apathetic) and Dimension 2 (knowledge building/surface learning). A pattern of low or dysfunctional perceived control contributed in the same direction as more negative affect in Dimension 3 (learned helplessness) and Dimension 2 (knowledge building/surface learning).

We also found support for Pekrun et al.'s (2006) findings that mastery and performance approach goal orientation are linked to different control perceptions and subsequent emotions. Mastery goal orientation always contributed to a dimension in conjunction with higher perceived control and positive class affect. Like Pekrun et al., we found that the performance approach goal orientation in this study also contributed in conjunction with higher perceived control and positive affect in Dimension 1 (good strat-

egy user/apathetic). Work avoidance goal orientation acted similarly to performance avoidance goal orientation in Pekrun et al.'s study. Higher work avoidance goal orientation contributed in the same direction as the dysfunctional control pattern and negative affect in Dimension 3 (learned helplessness) and the low perceived control and low positive affect in the apathetic end of Dimension 1.

Anxiety was not as clearly associated with perceived control. Consistent with previous control literature (Pekrun et al., 2006; Skinner, 1996), higher anxiety contributed in the same direction as dysfunctional control in Dimension 3 (learned helplessness) but did not contribute to any other dimension. The structure coefficient for anxiety was just below our cutoff in Dimension 1 (good strategy user/apathetic), suggesting, as Zeidner (1998) suggested, a potential positive role for anxiety in motivating control and strategic self-regulation, but this requires further research to substantiate.

## Discussion

### *The Multivariate Dimensionality of Control*

Our goal in this study was to further clarify the multidimensional nature of control in academic classroom settings by conducting a systematic, multidimensional examination of how control beliefs, in conjunction with other goal, motivational, and affect constructs, were related to academic strategic self-regulation. The results show that there is a dimensionality in the relations between control and strategic self-regulation that is distinct from the factorial dimensionality found for the component control beliefs themselves (e.g., Chapman et al., 1990; Skinner, 1996; Skinner et al., 1988; Walls & Little, 2005). Within these relationship dimensions, the association of any specific control belief to strategic self-regulation is dependent on the overall pattern of the other control beliefs, goal orientations, and affect present in the dimension.

Dimension 1 fit the traditional view of control (Chapman et al., 1990; Skinner, 1996; Skinner et al., 1988; Walls & Little, 2005; Weisz & Stipek, 1982). High control consisting of high agency (self-efficacy), high response–outcome contingencies (outcome expectancies), and internal means–ends contingencies (attribution to effort and ability) was associated with high use of self-regulated learning strategies, knowledge building, question asking, study time, and perceived study effort. Low control consisting of the absence of these beliefs was associated with no self-regulated strategy use, study effort, or active classroom engagement through question asking.

Dimension 3 also identified a well-established dysfunctional control pattern of low agency and agent–ends contingencies with means–ends contingencies for external causes paired with high response–outcome contingencies (outcome expectancies). Theorists (Bandura, 1997; Dweck & Leggett, 1988; Skinner, 1996; Stipek & Kowalski, 1989; Weiner, 1986) have noted the problematic nature of this pattern of control beliefs, which produces a learned-helplessness approach to self-regulation.

Dimension 2, however, identified patterns of control that have not been extensively discussed in the literature. Control in Dimension 2 seemed to contrast with effort. In general, control is thought to increase effort (Schmitz & Skinner, 1993; Shell & Husman, 2001; Skinner, 1996). In Dimension 2, however, higher agency,

agent–ends contingencies, and response outcome expectancies for learning were associated with more deep knowledge-building strategies without corresponding increases in general study time and effort or use of more general self-regulated learning strategies. Conversely, at the low end of the dimension, high means–ends contingencies to strategy use and effort, but low agency, agent–ends contingencies, and response outcome expectancies for learning were associated with exerting effort through higher use of general self-regulated learning strategies, study time, and low-level question asking but lower knowledge building and high-level question asking.

In relation to patterns of control, positive patterns of control appear to always include high self-efficacy for learning strategies and high outcome expectancy for learning. No other control belief was present in all positive control patterns. More negative or dysfunctional patterns of control appear always to have low self-efficacy for learning strategies, but no other control belief was present or absent in all negative patterns. Only three generalizations about relations between control and strategic self-regulation appeared to hold. First, higher self-efficacy for learning (agency) was always present in control patterns associated with more personal knowledge building and high-level question asking. Second, higher causal attribution to strategy use and effort was always present in control patterns associated with more use of self-regulated learning strategies and more study time. Interestingly, this held even if students had low self-efficacy for effectively executing the strategies they were using, as in the surface learning end of Dimension 2. Third, higher outcome expectancies were always present in control patterns associated with more positive strategic self-regulatory patterns, but not exclusively, as they also were in the control pattern associated with learned helplessness.

The gist of these findings is that the answer to “How does control influence academic strategic self-regulation?” is not straightforward. The answer depends on what pattern of control is involved and also on what type of strategic self-regulation one is referring to, especially effort expenditure versus deeper strategy use. The finding that effort expenditure is not always associated with every pattern of positive control perceptions and that control-motivated effort and strategy use may result in only surface level learning may help explain some of the anomalies in the link between control, effort expenditure, and achievement found by Schmitz and Skinner (1993). Like their results, the findings suggest that higher control does not necessarily lead to more effort, and neither does more effort lead to a strategic self-regulated pattern that is optimal.

### *The Interaction of Control, Goals, FTP, and Affect*

The results help fill the gap in empirical studies of the linkages between control and other motivational constructs noted by Walls and Little (2005). Control appears to be intertwined with both students' goal orientation and affect. Perception of high control always occurred in conjunction with mastery goal orientation and positive affect. These findings strengthen arguments for the primacy of mastery-oriented goals in achievement goal theory (e.g., Martin et al., 2003; Midgley et al., 2001; Pintrich, 2000a, 2000b, 2003). Conversely, work avoidance goal orientation always occurred in conjunction with low control perceptions, especially low self-efficacy, and in the case of learned helplessness, with a

dysfunctional pattern of high outcome expectancy and low self-efficacy. As hypothesized in self-determination theory (Reeve et al., 2004; Ryan & Deci, 2000), students who lack control do not appear to be motivated to set productive goals.

Performance approach goals were not strongly connected to patterns of control. The performance approach goals in this study occurred in conjunction with higher control only in Dimension 1 (good strategy user/apathetic). These findings support contentions that performance approach goals can be positive influences on students' self-regulation (Midgley et al., 2001; Pintrich, 2000a) but suggest that positive benefits are tied also to having mastery goals and to having high perceptions of perceived control. We did not assess performance avoidance goals, but the results suggest a potential role for these goals. The surface-learning end of Dimension 2 had a negative contribution from mastery goal orientation but did not have a positive contribution from any goal orientation. Looking at the rather negative control pattern of low self-efficacy and expectancy for success along with low outcome expectancies for learning or grades that characterized the surface-learning end of the dimension, we can speculate that the identified pattern of high causal attributions for strategy use and effort coupled with high self-regulated strategy use and study time could be supported by a performance avoidance goal of not appearing incompetent or stupid. These students did not appear to be studying and exerting effort for a positive reason, so perhaps they were doing so for a negative reason. This clearly deserves further study.

The findings strongly supported the connections between goal orientation, control, and affect proposed by Pekrun in his control-value theory of achievement emotion (Pekrun et al., 2006, 2002), as well as similar theoretical perspectives in self-determination theory (Reeve et al., 2004; Ryan & Deci, 2000) and self-worth theory (Covington, 2004). Positive affect appears to occur in conjunction with control exercised in the pursuit of mastery-oriented goals. No other combination of control and goal orientation was linked with high positive affect. Performance approach goal orientation did not appear to be uniquely linked with affect, as it only had a meaningful contribution to a dimension in conjunction with mastery goal orientation. Work avoidance goal orientation contributed in conjunction with high negative affect and anxiety in Dimension 3 (learned helplessness) and with lower positive affect in the apathetic end of Dimension 1. Work avoidance goal orientation also may have contributed in conjunction with lower anxiety (in opposition to its contribution with anxiety in Dimension 3) in the apathetic end of Dimension 1, but this potential linkage is only speculative because of the only marginal structure coefficient for anxiety in this dimension.

### *Dispositional Versus Class-Specific Beliefs*

Contrary to previous findings (De Volder & Lens, 1982; Miller et al., 1996; Husman et al., 2004; Shell & Husman, 2001), our findings were that FTP did not contribute meaningfully to any of the three canonical dimensions. Neither did locus of control, which has been shown to be associated with academic achievement in many studies (e.g., Heckhausen & Schulz, 1995; Shell & Husman, 2001; Stipek & Weisz, 1981). As noted by theorists (Bandura, 2001; Stipek & Weisz, 1981), a possible explanation for this is that control and other motivational constructs are psychologically hierarchical. From this perspective, students' self-regulated strategic

learning in a class would be most proximally motivated by their class-specific control perceptions, goal orientations, and affect, and these proximal motivators might wash out any influence from more dispositional, general beliefs like FTP, locus of control, or other self-system constructs. However, the proximal motivators themselves might be influenced by these dispositional-level constructs. These hierarchical patterns of influences deserve further study.

### *Final Conclusions*

The results suggest that motivation for academic strategic self-regulation derived from control, goal orientation, and affect is complex. Increasing or decreasing specific control beliefs or even the overall level of perceived control does not lead directly to any specific level of students' effort, strategy use, or self-regulation. Also, the influence of control is embedded within students' goal orientation and affective reactions to a course. We did not identify patterns of students' control-based motivation or strategic self-regulation that have not appeared in the literature; however, the findings help clarify how specific self-regulatory patterns, including negative or dysfunctional patterns, are motivated by specific constellations of control, goal orientation, and affect. The associations between these constellations and student strategic self-regulation do not fall along a single continuum. Rather, constellations of control, goal orientation, and affect appear to have qualitatively distinct multiple continuums of association, in which specific control beliefs, goal orientations, or affect may have different relationships to specific strategic self-regulatory behaviors and effort in one continuum than in another.

This study is limited in that we only examined college students. Future research is needed to determine whether similar dimensional continuums and relations between control and strategic self-regulation are present for younger students. The results confirm the need for the systematic, multivariate examination of control and other motivational constructs called for by control theorists (Little, 1998; Skinner, 1996; Skinner et al., 1988; Walls & Little, 2005). We could not have identified the canonical dimensions without a comprehensive inclusion of control, goal orientation, and affect measures, as well as a broad sampling of strategic self-regulatory and effort indicators. This multivariate examination needs to be continued and expanded to include other important motivational constructs that have been identified in the literature (e.g., Pintrich, 2003).

# What Makes Lessons Interesting? The Role of Situational and Individual Factors in Three School Subjects

Yi-Miau Tsai, Mareike Kunter, Oliver Lüdtke, and  
Ulrich Trautwein  
Max Planck Institute for Human Development

Richard M. Ryan  
University of Rochester

The present study investigated intraindividual variation in students' interest experience in 3 school subjects and the predictive power of perceived autonomy support and control. Participants were 261 students in 7th grade. After a survey of students' individual interests and other individual characteristics, repeated lesson-specific measures of students' interest experience and perceived autonomy support and control during instruction were obtained over a 3-week period. Hierarchical linear modeling showed 36%–45% of the variance to be located at the within-student level. Moreover, perceived autonomy support and control during lessons, as well as individual interest, predicted students' interest experience in the classroom.

**Keywords:** interest experience, individual interest, autonomy support, self-determination theory, repeated measurement design

Five minutes before the end of a lesson, students may be waiting impatiently for the bell to ring or be so engaged in the lesson that they are quite unaware of the time. Most students are probably familiar with both experiences. Whether or not a lesson was interesting is one of the key dimensions on which students judge their experience in the classroom. Indeed, the psychological state of being interested plays a major role in students' motivation and learning (Pintrich, 2003a; Urdan & Turner, 2005). Interest has been found to be associated with focused attention, higher cognitive functioning, and learning (Ainley, Hidi, & Berndorff, 2002; Köller, Baumert, & Schnabel, 2003; Krapp, Hidi, & Renninger, 1992). However, a precise understanding of how students' interest experiences emerge in classroom settings is lacking (Pintrich, 2003b). Moreover, although interest experience is influenced by a combination of stable individual characteristics and aspects of the current situation, most research to date has investigated these two sources of influence separately. The purpose of the present study is to investigate both sources of influence directly by assessing students' interest experience in different classroom learning situations. In particular, we examine how individual students' interest experience varies from lesson to lesson within a subject domain. Furthermore, we investigate whether interest experience can be

predicted by stable individual characteristics and by situational aspects that are specific to each lesson.

In the following sections, we first introduce the construct of *interest experience* as a temporary psychological state. We then discuss stable individual characteristics that are assumed to influence interest experience. Turning to situational factors, we next draw on the framework of self-determination theory to outline features of the instructional process that are theorized to enhance interest, focusing on various forms of autonomy support.

## Interest Experience

Interest experience is a psychological state that is characterized by an affective component of positive emotion and a cognitive component of concentration (Hidi & Renninger, 2006). When persons experience interest, their actions acquire an intrinsic quality; they are driven by enjoyment rather than external reasons (Krapp, 2002b). Interest is central to both intrinsic motivation and autonomous forms of extrinsic motivation (Deci, 1992; Ryan & Connell, 1989), and extreme forms of interest experience may be regarded as "flow" (Csikszentmihalyi, 1975).

States of interest arise through an interaction between the person and the surrounding context (Bergin, 1999; Sansone & Thoman, 2005). Consequently, several researchers have proposed that both situational and individual factors should be taken into account when trying to explain different levels of interest (Ainley, Hillman, & Hidi, 2002; Bergin, 1999; Hidi & Renninger, 2006; Sansone & Thoman, 2005). In the framework proposed by Krapp (2002b), the state of interest is assumed to be a function of two classes of distinct influences. The first influence comes from characteristics of the person him- or herself: stable features such as gender, prior knowledge, and experience and relatively stable preferences for certain content areas ("individual interest"). The second influence comes from characteristics of the situation. Certain features of the learning situation are assumed to be capable of arousing the individual's curiosity or interest, regardless of personal prefer-

---

ences (the “interestingness” of a situation). Examples of situational features assumed to trigger interest in the classroom include games and humor (Bergin, 1999).

Several interest researchers have used the term *situational interest* to refer to the psychological state of interest (e.g., Hidi & Anderson, 1992; Schraw & Lehman, 2001). The psychological state described—that is, a state of positive emotion and heightened concentration—is congruent with our description of interest experience. However, research on situational interest has tended to emphasize that the state is provoked by external and situational stimuli, rather than by individual variables (Hidi & Renninger, 2006). The term situational interest has sometimes even been used interchangeably with *interestingness of the situation* to describe the characteristics of tasks and texts that cause the state of interest (e.g., Schraw & Lehman, 2001). Moreover, it has been argued that situational interest occurs primarily in the early phases of interest development, when individual interest is absent or very low (Hidi & Renninger, 2006). Recently, Sansone and Thoman (2005) have therefore suggested that the term interest experience be adopted as a neutral description that does not refer to the genesis of the phenomenon. This term indeed seems better suited to describe the state of interest that occurs while individuals are engaged in learning activities and to convey the idea that the phenomenological state of interest observed may be an outcome of internal and/or external influences.

There is also conceptual overlap between interest experience and the task value component of expectancy-value theory (see Wigfield & Eccles, 2002) in terms of the intrinsic qualities shared by both concepts. Four components of task value can be identified: attainment value, intrinsic value, utility value, and cost. The largest overlaps are with attainment value and intrinsic value (see Eccles, 2005). Our conceptualization thus has much in common with task value as defined in expectancy-value theory, but it is not identical. First, the task value conceptualization is broader than our construct. Second, task values are typically investigated as rather stable beliefs, whereas interest experience is assumed to be a momentary state that may or may not last after an activity has been completed.

### Individual Characteristics That Influence Interest Experience

Interest experience is partly determined by individual characteristics such as gender and prior knowledge that the student brings to the instructional situation. For instance, girls are known to be more interested in certain topics (e.g., living things vs. inanimate objects) than boys (Hidi, 2006). Furthermore, students who lack necessary background knowledge and skills are less likely to experience interest in the classroom. In fact, prior knowledge has been shown to be associated with more interest experience (Alexander, Jetton, & Kulikowich, 1995). Such individual characteristics are fairly stable and unlikely to be altered by situational conditions.

The most discussed of these individual characteristics is the stable personal preference of individual interest (Krapp et al., 1992; Renninger, 2000). *Individual interest* (also referred to as *personal interest*) is defined as a relatively enduring disposition to attend to certain objects, stimuli, or events over time. It relates to specific content and is characterized by positive feelings and

values and accompanied by structured knowledge (Krapp, 2000, 2002b; Krapp et al., 1992; Renninger, 2000; Schiefele, 1991). Content-specific relationships evolve gradually from experience and biological predispositions; accordingly, the configuration of individual interest in different content areas differs across persons (Renninger, 2000). Some researchers regard individual interest as a motivational resource that helps people to cope with unfavorable learning conditions (Katz, Assor, Kanat-Maymon, & Bereby-Meyer, 2006; Silvia, 2006). When working on boring tasks, people with higher individual interest are more likely to engage in interest-enhancing strategies and to transform the activity into something more enjoyable (Sansone, Weir, Harpster, & Morgan, 1992).

Interest theory suggests that the psychological state of interest is automatically triggered when contents are perceived as relevant to one's individual interest. Interest experience is a momentary manifestation of this latent disposition (Krapp, 2002b). Indeed, experimental studies have demonstrated that interest experience can be predicted by individual interest. Particularly in the area of text interest, Ainley, Hillman, and Hidi (2002) found that secondary students with higher individual interest in literature already anticipated higher interest after being presented with the text titles and a few sentences.<sup>1</sup> The authors then used “online recording” methods (Ainley, Hillman, & Hidi, 2002, p. 421) to track participants' interest experiences during the reading process and found that these students continued to experience more interest, showed more persistence, and performed better in a recall test. Similarly, Hidi, Berndorff, and Ainley (2002) showed that general interest in writing is associated with enjoyment of writing activities. In a study involving logic problems, Katz et al. (2006) found that students with higher individual interest in logic questions were more willing to work on such tasks even when given no positive feedback. To date, most studies have been conducted in laboratory conditions, and little is known about the influential effects of prior individual interest in the classroom setting. It seems reasonable to predict that students' individual interest in the academic domain in question is likely to be activated and in turn influences students' interest experience.

At the same time, some findings indicate that individual interest alone is not sufficient to sustain interest experience throughout the learning process. Situational factors may also play a role in influencing students' interest experience over and above individual characteristics. For example, Ainley, Hillman, and Hidi (2002) found that text titles generated different levels of interest experience, regardless of participants' individual interest.

### Situational Factors That Influence Interest Experience

The second source of influence on interest experience is often described as the interestingness of the learning situation in terms of its content, topics, activities, and so forth. These situational factors are naturally assumed to be less stable and more easily manipulated than individual factors. Laboratory research in the area of text

<sup>1</sup> Ainley, Hidi, and Berndorff (2002) labeled this kind of interest that is elicited by a word or paragraph *topic interest*. According to this definition, topic interest is very similar to interest experience. We regard it as an interest experience that occurs in the specific situation of being presented with text and as an outcome of both individual and situational factors.

interest has identified various features of interestingness, such as the coherence, seductiveness, and vividness of the text (Schraw & Lehman, 2001). Mitchell (1993) identified “catch” and “hold” components of instruction that serve to enhance students’ interest state in mathematics classrooms. For instance, using puzzles and computers may initially catch students’ interest, and emphasizing meanings and encouraging students’ involvement can further hold their interest. Bergin (1999) outlined several situational factors that teachers can apply to enhance students’ interest in the classroom, such as hands-on activities, food, games, and puzzles. Consequently, many reform-based programs have endeavored to elicit interest through components such as videos, computer-based lessons, and authentic materials (e.g., Cognition and Technology Group at Vanderbilt, 1991).

The situational factors addressed thus far concern the surface level of learning activities, such as settings and materials, rather than interactional aspects that occur during the process of instruction. In the broader motivation literature, it has been argued that students’ perceptions of classroom instruction, especially of what teachers do and say, are associated with their motivation and behaviors (Ames, 1992; Stefanou, Perencevich, DiCintio, & Turner, 2004; Turner et al., 1998). With its focus on intrinsically motivated and autonomously regulated activities, self-determination theory (SDT) can provide valuable insights into students’ interest experience. Furthermore, SDT provides a rationale for how social and environmental support can promote autonomous behaviors and engagement in learning (Deci, Vallerand, Pelletier, & Ryan, 1991).

According to SDT, intentional behaviors can be motivated by either autonomous or controlled forms of regulation. Autonomous forms of regulation include both intrinsic motivation, or behavior energized by its inherent satisfactions, and identified or integrated forms of extrinsic motivation. Here, the individual identifies with the personal importance of a behavior or assimilates its regulation to the self (Ryan & Deci, 2000a), meaning that regulation is autonomous, volitional, and valued by the self (Deci et al., 1991). Research in SDT has also repeatedly confirmed that autonomously regulated behaviors are characterized by the experience of interest (Deci, 1992; Grolnick & Ryan, 1987). By contrast, behaviors experienced as controlling (e.g., externally regulated or introjected regulations) are typically not associated with either interest or task enjoyment (Ryan & Connell, 1989; Ryan & Deci, 2000a). Accordingly, the level of autonomy support in the classroom is a key factor for understanding students’ interest (Reeve, 2002). Teachers can create an autonomy-supportive climate by attempting to understand students’ feelings and thoughts about learning tasks and by supporting students’ personal growth (Assor, Kaplan, & Roth, 2002). Specifically, autonomy-supportive instructional behaviors include listening, asking questions about students’ wishes, responding to students’ questions and acknowledging the students’ perspective, allowing students to work on their own, using praise as informational feedback, and offering encouragement (Reeve, Bolt, & Cai, 1999; Reeve & Jang, 2006; Williams & Deci, 1996).

Experimental, survey, and longitudinal studies have provided evidence to confirm the positive effects of this type of autonomy support on students’ interest and engagement (Deci et al., 1991; Krapp, 2002a, 2005; Reeve, 2002; Ryan & Deci, 2000b; Trouilloud, Sarrazin, Bressoux, & Bois, 2006; Urdan & Turner, 2005). Findings on the effects of autonomy-supportive instructional be-

haviors in authentic classroom settings are of particular interest for the current investigation (Reeve, 2002; Reeve & Jang, 2006). Students whose teachers are more autonomy oriented in their instructional style (Black & Deci, 2000; Deci, Schwartz, Sheinman, & Ryan, 1981; Ryan & Grolnick, 1986) or are given training in autonomy support (Reeve, Jang, Carrell, Jeon, & Barch, 2004) have been found to show higher intrinsic motivation, more positive emotion, and more active involvement.

In reality, however, the social arrangement of the classroom, with teachers as instructors and students as “receivers,” often leads teachers to neglect students’ need for autonomy and to resort to overly directive or controlling instructional behaviors (Assor, Kaplan, Kanat-Maymon, & Roth, 2005). During instruction, these behaviors include disrupting the students’ natural rhythm of learning (not letting them work at their preferred pace), using directive commands, making “should” statements, and asking controlling questions (see Assor et al., 2002; Reeve & Jang, 2006). These teaching behaviors have been shown to impair students’ sense of autonomy and to hinder intrinsic motivation, engagement, effort, and persistence (Ryan & Grolnick, 1986). From a self-determination perspective, these behaviors are autonomy suppressing in that the teachers fail to support their students’ need for autonomy. Moreover, these behaviors reflect teachers’ attempts to impose a teacher-centered agenda by having an instantaneous impact on students’ behavior and leaving students no room for self-reliant behaviors (Assor et al., 2002; Grolnick & Ryan, 1987). Assor et al. (2005) have demonstrated that controlling instructional behaviors and autonomy support are perceived as distinct aspects of teachers’ behavior. Controlling instructional behaviors, in particular, have a unique effect in inducing the negative emotions of anger and anxiety during the learning process (Assor et al., 2005).

Cognitive autonomy support has recently been proposed as another dimension of autonomy support (Stefanou et al., 2004). Whereas autonomy-supportive climate and controlling instruction focus on social interaction, cognitive autonomy support emphasizes the support provided for students’ engagement in cognitive activities. It has been proposed that students experience a sense of personal control at the cognitive level when teachers explain the purposes of the task at hand and its links to the learning concepts and scaffold students’ understanding by activating prior knowledge or increasing personal relevance (Schraw & Lehman, 2001; Stipek, 1996, 2002; Turner & Meyer, 2004). Despite the claim that cognitive autonomy support “truly leads to psychological investment in learning” (Stefanou et al., 2004, p. 101), there has as yet been little direct empirical investigation of the concept in classrooms. However, instructional research provides indirect support for this claim. For instance, enhancing students’ active cognitive participation has been shown to foster learning and to increase intrinsic interest and enjoyment (Brophy, 1999; Kunter & Baumert, 2006a; Stipek, 1996, 2002; Turner, 2001; Turner et al., 1998; Vermunt & Verloop, 1999). In mathematics classrooms, students show more involvement and positive affect when teachers scaffold learning and transfer responsibilities to students (Turner et al., 1998).

Within the framework of self-determination theory as reviewed above, we can thus identify three features of the instructional process that may affect students’ intrinsic motivation and interest experience: autonomy-supportive climate, controlling behaviors, and cognitive autonomy support. In the present investigation, we

conceptualize all three aspects as situational variables that may differ from lesson to lesson, rather than as features of a stable motivating style (Reeve, 1998). Evidence from experimental designs has repeatedly shown that slight manipulations in autonomy-supportive instruction can significantly affect participants' interest (Deci, Eghrari, Patrick, & Leone, 1994; Reeve, Jang, Hardre, & Omura, 2002; Vansteenkiste, Simons, Lens, Soenens, & Matos, 2005). In the present study, we examine all three instructional aspects simultaneously to determine their distinct influences on students' interest experience in authentic classroom settings.

### The Present Study: Linking Situational and Individual Factors in an Intraindividual Approach

The present study investigates students' interest experience in the real-life classroom environment, examining both the situational and the individual factors that contribute to interest experience in a lesson. An intraindividual approach seemed appropriate to determine the relative effects of situational and individual factors simultaneously. In a repeated-measures design, we followed a group of students over a 3-week period, assessing their interest experience immediately after lessons. Situational factors assumed to vary across lessons were also assessed repeatedly. Multilevel modeling techniques were then applied to analyze intraindividual data and to estimate the effects of situational and individual factors simultaneously. Similar methods have been applied to investigate multilevel data in domains such as individuals' differentiated attachment patterns to different targets (La Guardia, Ryan, Couchman, & Deci, 2000), students' homework effort in different subjects (Trautwein & Lüdtke, 2007), and self-evaluation and mood in diary studies (e.g., Armeli, Carney, Tennen, Affleck, & O'Neil, 2000; Möller & Husemann, 2006).

Specifically, the present study has the following objectives. First, using a repeated-measurement design to assess students' interest experience in real-life classroom settings over time, the study offers unique opportunities to examine intraindividual variation in students' interest experience. Emotional experience has been shown to fluctuate naturally over time (Eid & Diener, 1999); therefore, it seems worthwhile to examine the extent of intraindividual variation in students' interest experience in a structured learning situation such as the classroom.

The second objective was to examine the effects of three aspects of autonomy support as situational factors. On the basis of SDT, we expected variation in students' interest experience across lessons to be predicted by the level of autonomy support experienced in the lesson, not only in terms of autonomy-supportive climate and controlling behaviors but also in terms of cognitive autonomy support. In addition, we explored whether these situational effects applied equally across all students.

Third, beyond situational factors, we examined the individual factors of gender, domain-specific grades, and individual interest. On the basis of interest theory, we expected individual interest as a stable personal preference to be associated with interest experience in situations whose content was perceived to be related. In other words, students' stable subject-specific individual interest was expected to impact their interest experience during lessons in that subject.

To examine the generality of the above hypotheses across different academic domains, we collected student data on three school

subjects. We purposely chose the core school subjects of mathematics, native language instruction (i.e., German), and the second foreign language. At least 4 lesson hours per week were dedicated to each of these compulsory subjects. It is therefore plausible to assume that students' experiences in these lessons are important for their general well-being in school. We chose the second foreign language (rather than English) as a new subject that had only recently been introduced to the students' timetables to contrast with the two old subjects of mathematics and German, in which students had several years' learning experience. This approach allows us to examine whether interest fluctuation is higher in subjects in which students have little prior experience.

## Method

### Participants

Participants were 261 (57% girls) seventh-grade students in Germany. The mean age was 12.3 years ( $SD = 0.5$ ). The vast majority of participants were of European origin ( $> 95\%$ ) and reported speaking German with at least one of their parents (91.2%). Of those who did not speak German at home, 30% reported Turkish and 35% Polish as the primary home language. Students' participation was voluntary and required parental consent; 90% of target students participated. Students were recruited from nine classes in two public *gymnasium* schools in Berlin. *Gymnasium* is the highest track in the three-tier secondary school system in Germany; about one-third of students are enrolled in *gymnasium* schools based on their achievement in elementary school.

### Procedure

The study consisted of a pretest to assess individual characteristics and a lesson-specific repeated measurement phase. In all cases, assessments were administered to classroom units. The pretest was administered in the 4th week of the school year. Lesson-specific repeated measurements began 1 week later and continued for 3 consecutive weeks. The timetables of the nine participating classes were obtained in advance in preparation for the lesson-specific repeated measurements. A maximum of four mathematics lessons, four German (native language instruction) lessons, and four to five second foreign language lessons were scheduled per week. All subjects were taught by different teachers. Data were obtained on all mathematics, German, and second foreign language lessons that took place during the 3-week assessment period. Only lessons that coincided with special events (e.g., class trip) or that did not involve regular instruction (e.g., whole lesson used for an exam) were not assessed.

Lesson-specific measures comprising 33 items were administered at the end of each lesson assessed. The teachers concluded the lesson 3–5 min earlier than scheduled, and research assistants then entered the classroom to administer the lesson-specific questionnaire. Students were instructed to respond on the basis of their experiences during that specific lesson. The first lesson assessed included a 10-min training unit to ensure that all participants understood the questionnaire and procedure. It took students less than 5 min to complete the questionnaires.

## Measures

*Lesson-specific measures (LSM).* Students' interest experience and autonomy-related perceptions in particular lessons were measured using LSM. The same measures were used for mathematics, German, and second foreign language lessons. In designs such as daily diary studies, short instruments are often used to reduce the burden of repeated queries on participants. Some studies have relied on one- or two-item measures (e.g., Birnbaum, Reis, Mikulincer, Gillath, & Orpaz, 2006; Finkel, Burnette, & Scissors, 2007). With a view to the reliability of the measures administered in the present study, we used four to six items to assess each construct measured in LSM (all LSM items are listed in the Appendix).

*Interest experience.* Based on Krapp's (2002b) conceptualization, the interest experience measure comprised an emotion component and a value component. The scale contained a total of five items assessing the emotion component ("The topic was interesting to me," "I liked the topic") and the value component ("The topic was meaningful to me," "I saw what the teacher taught us can be useful in real life," and "It was important to me that I thoroughly understand my class work"). Responses were given on a 6-point scale that ranged from 1 (*disagree strongly*) to 6 (*agree strongly*). We conducted exploratory factor analyses to examine whether the items formed a unidimensional scale for interest experience. The factor analyses<sup>2</sup> showed strong support for a unidimensional factor structure, indicating that different aspects of interest experience form one construct in the LSM. The mean of all five items was therefore calculated separately for each lesson-specific measurement to form the interest experience variable. Cronbach's alpha as an index for internal consistency was calculated separately for each lesson-specific measurement; the mean Cronbach's alpha was .90 (range = .87–.93) for mathematics, .90 (range = .86–.92) for German, and .91 (range = .87–.93) for the second foreign language.<sup>3</sup>

The LSM also assessed the three aspects of autonomy support. We measured these variables from the students' perspective because individual students may experience different amounts of support or perceive the climate and instruction differently, even in the same classroom.

*Perceived autonomy-supportive climate* was measured by a short, six-item version of the Learning Climate Questionnaire (Williams & Deci, 1996). Items were adapted to the lesson situation (e.g., "I felt that my teacher provided me choice and options" and "I felt understood by my teacher"). Responses were given on a 6-point scale that ranged from 1 (*disagree strongly*) to 6 (*agree strongly*).

*Perceived controlling behaviors* were operationalized as overt and inappropriate teaching behaviors that disrupted students' natural rhythm in terms of workload or pacing and that left students little room for self-reliant behaviors. As well as behaviors that have previously been investigated as subscales of autonomy-suppressing behaviors, such as intrusive and overly demanding instructional behaviors, we included items tapping inappropriate instructional behaviors in broader terms (Assor et al., 2002). Four items tapped students' perceptions of these behaviors (e.g., "Our teacher expected split-second answers" and "Our teacher was mean to one of the students").

*Perceived cognitive autonomy support* measured instruction that involves students cognitively and scaffolds their conceptual un-

derstanding with five items (e.g., "More than one student presented their solution to a task" and "Our teacher emphasized the relations between the topics discussed"; Kunter & Baumert, 2006b).

We conducted exploratory factor analyses separately for each assessment of interest experience to examine the factor structure underlying all autonomy-related items. A total of 27 exploratory factor analyses (9 analyses for each of the three subjects) were conducted for the autonomy-related items. As expected, a three-factor solution emerged. Factor analyses with varimax rotation yielded eigenvalues between 4.06 and 7.46 for the first principal component and explained between 36% and 53% of the variance. This component included items pertaining to perceived autonomy-supportive behaviors. The eigenvalues of the second principal components were between 1.80 and 2.39 and explained between 13% and 18% of the variance. This component included items on perceived cognitive autonomy support. With one exception, the eigenvalues of the third principal component were also larger than 1 (range = 0.98–1.7) and explained between 7% and 12% of the variance. This component included items on perceived controlling behavior. The eigenvalues of subsequent principal components were substantially lower, as was the explained variance. The eigenvalues of the fourth principal component were between .82 and 1.14, and the explained variance was between 6% and 9%. This component included one or two items measuring controlling behaviors. Overall, 22 of the 27 (81%) exploratory factor analyses yielded three principal components larger than 1. The other five factor solutions yielded four principal components larger than 1. Based on the factor solutions, three variables of lesson-specific autonomy-related perceptions were thus calculated for each lesson-specific repeated measurement: perceived autonomy-supportive climate, perceived controlling behaviors, and perceived cognitive autonomy support. These three scales were moderately correlated with each other: Larger correlations were found between perceived autonomy-supportive climate and perceived cognitive autonomy support ( $r \leq .35$ ); the correlations with perceived controlling behaviors were below .11 (see the correlations above the diagonals in Table 1). Cronbach's alpha was calculated for

<sup>2</sup> Exploratory factor analyses were conducted separately for each measurement at the lesson level. Nine exploratory factor analyses were conducted for each school subject (only measurement points containing data from at least 100 participants were analyzed). The same pattern emerged for all three subjects. In mathematics lessons, only the first principal component had eigenvalues larger than 1 (range = 3.7–4.4), with explained variance ranging between 62% and 73%. The eigenvalues (range = 0.55–0.93) and explained variance (below 15%) for the second principal component were much lower. Likewise, in German lessons, only the first principal component had eigenvalues larger than 1 (range = 3.5–4.4), with explained variance ranging between 58% and 73%. The eigenvalues (range = 0.56–0.95) and explained variance (below 16%) for the second principal component were much lower. Finally, in the second foreign language, only the first principal component had eigenvalues larger than 1 (range = 3.7–4.7), with explained variance ranging between 61% and 78%. The eigenvalues (range = 0.56–0.77) and explained variance (below 13%) for the second principal component were much lower.

<sup>3</sup> Applying the same rule as in the exploratory factor analyses, Cronbach's alphas were calculated separately for measurement points on the lesson level containing data from at least 100 participants. In total, nine Cronbach's alphas were calculated for each school subject.

Table 1  
Correlations Among Lesson-Specific Measures and Individual Characteristics

Variable	Mathematics				German				2-language			
	1	2	3	4	1	2	3	4	1	2	3	4
Lesson-specific measures												
1. Interest experience	—	.35**	-.12**	.34**	—	.36**	-.09**	.32**	—	.39**	-.19**	.33**
2. Autonomy-supportive climate	.57**	—	-.05*	.34**	.63**	—	-.04	.35**	.58**	—	-.10**	.34**
3. Controlling behaviors	-.19*	.18	—	.07**	.04	.20**	—	.11**	-.12*	.18**	—	.08**
4. Cognitive autonomy support	.66**	.68**	.01	—	.54**	.71**	.26**	—	.55**	.70**	.16**	—
Individual characteristics												
Individual interest	.51**	.26**	-.11	.26**	.42**	.27**	.01	.16**	.52**	.27**	-.10	.21**
Subject-specific school grade	.13*	.03	-.04	.07	-.02	.03	-.11	-.02	—	—	—	—

Note. For the lesson-specific measures, correlations above the diagonals represent within-person correlations and correlations below the diagonals represent between-person correlations. Dashes indicate that no data were available. 2-Language = second foreign language.

\*  $p < .05$ . \*\*  $p < .01$ .

each measurement at the lesson level as an index of internal consistency. For mathematics, German, and the second foreign language, respectively, the mean  $\alpha = .92$  (range = .86–.96), .92 (range = .86–.94), and .92 (range = .84–.94) for perceived autonomy-supportive climate; .66 (range = .59–.73), .64 (range = .59–.70), and .69 (range = .60–.75) for perceived controlling behaviors; and .76 (range = .62–.85), .76 (range = .58–.83), and .76 (range = .65–.84) for perceived cognitive autonomy support.

### Measures of Individual Characteristics

Individual characteristics such as individual interest, school grades, and gender were assessed at the pretest. A 7-item scale was used to assess individual interest in mathematics, German, and the second foreign language (Ramm et al., 2006). These items (e.g., “I do [subject matter], because it is fun for me” and “For me, [subject matter] is personally important”) were based on earlier work (e.g., Marsh, Trautwein, Lüdtke, Köller, & Baumert, 2005). Students responded to each question in separate columns for mathematics, German, and the second foreign language. Responses were given on a 6-point scale anchored by the end points 1 (*disagree strongly*) and 6 (*agree strongly*). Cronbach’s alphas for mathematics, German, and the second foreign language were .92, .87, and .91, respectively. Students were also asked to report the mathematics and German grades they had been awarded on their sixth-grade report cards (i.e., at the end of elementary school). Elementary school grade for second foreign language was not available because the students had not been introduced to this subject until the seventh grade. The German grading system ranges from 1–6, with smaller numbers indicating better performance. To maintain consistency with the other scales, we reverse coded the grades such that a higher value indicates better performance. Gender was coded 0 for female and 1 for male.

### Statistical Analysis

**Analyzing hierarchically structured data.** The repeated measures design results in a two-level hierarchical structure with LSMs nested within each individual student. At the within-student level (Level 1), we tested a number of repeated LSMs collected for each student over the 3-week period. At the between-student level

(Level 2), we assessed variations in student characteristics including gender, individual interests, and school grades.

Hierarchical linear modeling (HLM; Raudenbush & Bryk, 2002) is capable of handling hierarchically structured data that violate the assumption of independence. Furthermore, HLM identifies variance in multiple levels of the data—in our case, at the within- and between-students levels. Moreover, HLM allows simultaneous estimation of effects of predictors from different levels. Detailed descriptions of the models are provided with the results. All analyses were conducted using the program HLM (version 6; Raudenbush, Bryk, Cheong, & Congdon, 2004).

**Treatment of missing values.** Our data set contained three types of missing data: first, missing responses to some of the items in the LSMs; second, missing responses to measures of individual characteristics in the pretest; and third, missing data caused by students’ absence in some of the lesson-specific assessments. Because HLM allows unequal numbers of observations for each individual, missing data of the third type were not a problem. The first two types of missing data were not considered problematic because the rate for each was less than 3%. Different approaches have been shown to produce satisfactory results when the missing rate is below 5% (Graham, Cumsille, & Elek-Fisk, 2003). In the present study, a multiple imputation procedure was chosen (Peugh & Enders, 2004). All available data from the lesson-specific and pretest measures were used to estimate the missing values, including demographic and motivational variables that were not used in the present investigation. The NORM software (Version 2.03; see Schafer & Graham, 2002) was used to generate five data sets in which missing data were replaced by estimated values. All HLM analyses were conducted with the five complete data sets, and combined results are reported (Schafer & Graham, 2002). The descriptive statistics reported below are based on the raw data set.

## Results

### Descriptive Analyses

A total of 6,468 completed lesson-specific questionnaires were obtained; students participated in an average of 8.4 measurements

(range = 5–11) in mathematics lessons, 8.0 measurements (range = 2–10) in German lessons, and 8.4 measurements (range = 6–11) in second foreign language lessons.

For exploratory purposes, mean values of lesson-specific measurements were calculated for each individual student for mathematics, German, and the second foreign language separately. Descriptive statistics for these person-mean LSMs are presented in Table 2. In general, students' person-mean scores on interest experience tended toward the positive end of the 6-point scale. In terms of autonomy support, within-person means for autonomy-supportive climate and cognitive autonomy support were around the midpoint of the scale, whereas person-mean scores on perceived controlling behaviors were low.

Intercorrelations among LSMs and individual characteristics are presented in Table 1. Two types of correlations were computed for the LSMs: between-person correlations and within-person correlations. Between-person correlations were calculated using the mean scores for each student. As shown under the diagonals in the top panel of Table 1, person-mean interest experience was moderately associated with person-mean autonomy-supportive climate ( $r \geq .57$ ) and person-mean cognitive autonomy support ( $r \geq .54$ ), indicating that students who reported higher average interest experience also reported higher average autonomy-supportive climate and cognitive autonomy support. Findings on the association between person-mean interest experience and person-mean controlling behaviors were mixed across three subjects.

Regarding the relations to individual characteristics, students' person-mean interest experience correlated significantly with individual interest in the corresponding academic domain as measured in the pretest ( $.42 \leq r \leq .52$ ). Smaller but significant correlations were found between autonomy-supportive climate and perceived cognitive autonomy support and individual interest ( $.16 \leq r \leq .27$ ). No significant associations were found between perceived controlling behaviors and individual interest.

Second, within-person correlations were calculated using all lesson-specific data. These within-person correlations indicate the correlation structure across lessons for individual students. In order to partial out the between-person variance, each student's person-

mean value was subtracted from his/her raw scores, such that every student had the new mean value of zero. Next, all lesson-specific scores from students were used to calculate the correlations. As shown above the diagonals in the top panel of Table 1, interest experience correlated significantly with all three autonomy-related perceptions. It has been suggested that the within-person correlation structure may reveal different results from the between-person correlation structure (Michela, 1990). In our case, the within-person correlations showed that students reported less interest in lessons where they perceived more teacher control, but this association was not always significant across school subjects in the between-person correlations. In the next section, we examine the within-student and between-student variance simultaneously with HLM models.

Examining Intraindividual Variation in LSMs

We used an unconditional model to examine variance in interest experience at the within-student and between-student level. If a student tends to produce similar responses across lessons, the proportion of variance at the within-student level will be low. Separate models were calculated for mathematics, German, and the second foreign language. The results show that the proportion of variance at the within-student level was substantial: 36% in mathematics, 45% in German, and 36% in the second foreign language. Therefore, our findings supported the hypothesis of lesson-to-lesson variation in students' interest experience.

In addition, unconditional HLM models were applied to analyze the variance components of the three autonomy-related LSMs. Proportions of within-student variance were 36%–38% for perceived autonomy-supportive climate, 52%–58% for controlling behaviors, and 44%–50% for cognitive autonomy support. The sizeable variances in both interest experience and the three predictors justified our further attempts to predict interest experience by reference to three autonomy-related perceptions at the within-student level.

We begin with a detailed description of the HLM analyses incorporating predictors from both levels. The analyses served two main objectives. First, we examined whether students' interest experience during lessons could be predicted by situational factors of the lesson (i.e., within-student level predictors). Second, we investigated whether individual differences in interest experience could be predicted by student characteristics (i.e., between-student level predictors). Models were fitted using restricted maximum likelihood estimation. The results for within-student and between-student level predictors are described in the following sections.

First, at the within-student level, we investigated how interest experience is predicted by the three autonomy-related perceptions using the regression equation below.

Interest<sub>ij</sub> =  $\pi_{0i}$  +  $\pi_{1i}$ Autonomy +  $\pi_{2i}$ Control +  $\pi_{3i}$ Cognitive +  $\epsilon_{ij}$ ,

where Interest<sub>ij</sub> is the interest experience of the *i*th student in the *j*th lesson;  $\pi_{0i}$  represents the intercept of the *i*th student;  $\pi_{1i}$ ,  $\pi_{2i}$ ,  $\pi_{3i}$  represent the regression coefficients for the three autonomy-related perceptions; and  $\epsilon_{ij}$  is random within-person error. All three predictors were group-mean centered (here, person centered). This procedure tests specifically whether interest experience is ex-

Table 2  
Person-Mean Lesson-Specific Measures and Measures of Individual Characteristics

Variable	Mathematics		German		2-language	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Lesson-specific measures						
PM Interest experience	3.94	1.18	3.95	1.09	4.11	1.15
PM Autonomy-supportive climate	3.05	1.13	3.16	1.15	3.15	1.12
PM Controlling behavior	1.95	0.73	1.71	0.62	1.92	0.70
PM Cognitive autonomy support	3.46	1.04	3.11	1.01	3.14	1.03
Individual characteristics						
Individual interest	3.90	1.34	3.82	1.06	4.57	1.11
Subject-specific school grade	4.84	0.77	4.99	0.55	—	—

Note. All items were rated on a 6-point scale with 6 as the highest value. Dashes indicate that no data were available. PM = person-mean; 2-language = second foreign language.

plained by different autonomy-related perceptions relative to an individual student's own baseline. Alternative procedures (e.g., no centering or grand-mean centering) are less suitable for the present investigation, because the results might be caused partly by students' different baselines. The present approach allows effects purely at the within-student level to be disentangled.

Turning to the between-student level, the parameters are further modeled by individual characteristics as follows:

$$\pi_{0i} = \gamma_{00} + \gamma_{01}\text{Male} + \gamma_{02}\text{IndInt} + \gamma_{03}\text{Grade} + \zeta_{0i},$$

$$\pi_{1i} = \gamma_{10},$$

$$\pi_{2i} = \gamma_{20},$$

$$\pi_{3i} = \gamma_{30}.$$

The first equation predicts the intercept  $\pi_{0i}$ —the average interest experience of the  $i$ th student—derived from a Level 1 equation. Here, it is predicted by the individual characteristics of gender, individual interest, and school grade. The  $\gamma_{00}$  represents the grand mean of the sample accounting for the effects of gender on the students' mean interest experience ( $\gamma_{01}$ ), the effects of individual interest and prior school grades ( $\gamma_{02}$  and  $\gamma_{03}$ ). The  $\zeta_{0i}$  reflects random error at the between-student level. The next three equations indicate that the within-student level regression parameters  $\pi_{1i}$ ,  $\pi_{2i}$ , and  $\pi_{3i}$  are treated as fixed effects and thus only predicted by the intercepts  $\gamma_{10}$ ,  $\gamma_{20}$ , and  $\gamma_{30}$ . All continuous variables were z-standardized prior to multilevel modeling.

### Predicting Interest Experience With Situational Factors

Model 1 tested the effects of the three within-student level predictors that are presented in Table 3. The three school subjects are modeled separately. The hypothesized associations between the three autonomy-related perceptions and the change in students'

interest from lesson to lesson were all supported. As shown, students experienced more interest in lessons where they perceived (relative to their own baseline) a more autonomy-supportive climate, more cognitive autonomy support, and less controlling behavior. In mathematics lessons, for example, autonomy-supportive climate and cognitive autonomy support had moderate effects, with  $B$  values of .25 and .23, respectively. In other words, one standard deviation increase in autonomy-supportive climate and cognitive autonomy support was associated with one quarter of a standard deviation increase in interest experience. The effect of controlling behavior was statistically significant but smaller, at  $B = -.10$ . A consistent pattern of results was found across all three subjects. Overall, over 19% of the variance at the within-student level was explained by the three autonomy-related perceptions.

### Predicting Interest Experience With Between-Student-Level Factors

Turning to the between-student level, we examined whether the differences in students' average interest experience could be predicted by the individual characteristics of gender, individual interest, and school performance. As shown in Table 3 (Model 1), we found a unique effect of individual interest among the three individual characteristics, with coefficients between .35 and .46 across the three subjects. Interest experience was thus significantly predicted by individual interest in the subject. There were no significant effects of gender or school grades on interest in the subject. Overall, the individual predictors explained 27% of the variance at the between-student level in mathematics, 19% in German, and 27% in the second foreign language.

One open question remains regarding the effects of individual characteristics. Is it possible that some students reported higher average interest experience because lessons were constantly more

autonomy supportive for them? Group-mean centering had removed the information on students' baseline lesson perceptions. Therefore, in order to examine the effect of individual characteristics after controlling for the general level of the three autonomy-related lesson perceptions, we followed the recommendation by Kreft and de Leeuw (1998, p. 108) and added the subtracted mean structure of the three group-mean centered predictors back into the models as between-student predictors. Another set of HLM models (Model 2) was thus specified that included averaged within-student level predictors at the between-student level.

In Model 2, the significance pattern of individual characteristics effects remained the same for all school subjects. The effects of individual interest decreased but remained statistically significant; the effects of gender and school grade remained nonsignificant. The regression coefficients for individual interest ranged between .24 and .29 in three school subjects. The coefficients indicated that, even when the overall level of the three autonomy-related lesson perceptions was controlled, students' individual interest was still related to interest experience. The overall variance explained by between-student level predictors increased by at least 30% when the person means of three autonomy-related lesson perceptions were included.

#### *Examining Variation in the Effects of Situational Factors Across Students*

Thus far, the HLM models have assumed that the effects of within-student level predictors are the same for all students. To explore whether the effects of autonomy-supportive climate, controlling behavior, and cognitive autonomy support apply equally to all students, we conducted an additional set of so-called random effect models. In between-student-level HLM equations, random components were specified for  $\pi_{1i}$ ,  $\pi_{2i}$ , and  $\pi_{3i}$ . In other words, a total of nine random components were examined for all school subjects. The results of the random effect model showed that all nine variance components for within-student-level regression coefficients were significant, indicating that the effects of autonomy-supportive climate, cognitive autonomy support, and perceived controlling behaviors on interest experience vary substantially between students. To gain insight into the magnitude of variation, we followed the recommendation of Raudenbush and Bryk (2002, p. 78), and calculated the 95% plausible value range of the slopes using information on the average slope and the slope standard deviation. The largest range of effect was found for autonomy-supportive climate in mathematics lessons: The average slope was 0.27 and the standard deviation was 0.26. It follows that the effect ranged between  $0.27 - 2 \times 0.26 = -.25$  and  $0.27 + 2 \times 0.26 = 0.79$  for approximately 95% of the students in the present study. The smallest range of effect was found for perceived controlling behaviors in mathematics lessons, at between  $-0.36$  and  $0.16$ .

These results revealed meaningful difference across students that warrants further examination. We ran exploratory models in an attempt to explain this variation in terms of students' individual characteristics. Specifically, we examined whether these differences in the slopes across students were explained by gender, individual interest, or school grades. Two statistically significant results emerged. In mathematics lessons, the effect of perceived controlling behaviors was moderated by individual interest ( $B = -.05$ ,  $p = .029$ ), and in second foreign language lessons, the effect

of autonomy-supportive climate was moderated by individual interest ( $B = -.10$ ,  $p = .002$ ). These findings indicated that students with higher individual interest were less affected by the controlling behaviors of their mathematics teachers or by an autonomy-supportive climate in second foreign language lessons. Overall, rather little of the difference across students was explained by the three individual characteristics.

## Discussion

The multilevel analyses conducted to investigate students' interest experience in authentic learning situations revealed three main findings. First, there was substantial intraindividual variation in students' interest experience in day-to-day classroom learning. Second, the pattern of variation was predicted by the situational factors of autonomy supportive climate, controlling behaviors, and cognitive autonomy support in lessons. The effects of situational factors were consistent across the three subjects investigated. Third, students who started with higher domain-specific individual interest had higher interest experience in average lessons.

#### *Interest Experience in Lessons: Intraindividual Variability*

The present study is among the first to investigate how students' interest experience emerges and endures in the classroom over a relatively short period of time. Over three weeks, in an average of eight lessons, variance in interest experience at the within-student level accounted for between 36% and 44% of the overall variance. Whereas between-student variance indicates that interest experience differs from one student to another, within-student variance indicates that interest experience also differs within students from one lesson to another. Moreover, the amount of intraindividual variation observed was very similar across the three subjects examined, although it was slightly higher in German lessons (44%). The extent of variation in the structured learning condition of the classroom thus seems to be similar across domains. To counter the possibility that such within-student variation is mainly due to measurement error, we used a 5-item scale with good internal reliability in the present study. Furthermore, the finding that intraindividual variability covaries with lesson perceptions also indicates that the pattern of results is more meaningful than random fluctuation.

The psychological state of interest is not a fixed entity. Even individuals who generally enjoy reading are more interested in some texts or topics than others (Ainley, Hidi, & Berndorff, 2002; Ainley, Hillman, & Hidi, 2002). To date, most research on interest variation has been carried out in laboratory settings and has focused on text-based processing. The present findings confirm that variation in interest state is observable not only in laboratory settings but also in authentic classrooms across a wide range of topics and activities. The students in our sample, who had six years of classroom learning experience and had already attended numerous lessons in certain subjects, nevertheless experienced some lessons as more interesting and engaging than others. These results challenge the beliefs of some teachers that many students are just not interested and cannot be motivated. The finding that students are sensitive to the learning conditions afforded by the teacher is encouraging for teachers. At the same time, the challenge remains

of how to create an interesting and motivating learning environment.

### *Instructional Features and Interest Experience*

Which instructional features make a lesson substantively different from others? SDT proposes that individuals have a basic need to feel self-determined or autonomous, and that teachers' autonomy support during instruction can facilitate satisfaction of this psychological need (Reeve, 2002). Teachers' autonomy-supportive behaviors have previously been shown to generate more engagement and effort among students (Reeve et al., 2002, 2004). Our study extends these beneficial effects to include students' interest experience. Lessons in which students perceive the teacher taking their perspective and understanding what they want (i.e., an autonomy-supportive climate) are associated with higher interest experience; in contrast, lessons in which teachers disrupt students' natural learning rhythms and do not allow time for reflection (i.e., controlling behaviors) were associated with lower interest experience. The factor solution and small within-person correlations showed that teachers' controlling behavior is a distinct construct from autonomy-supportive teacher behaviors. Moreover, teachers' controlling instructional behaviors seem to be associated with negative student emotions, such as anxiety in the classroom (Assor et al., 2005; Tsai, Kunter, Lüdtke, & Trautwein, 2007). Following the conceptualization of Assor et al. (2002), we measured the construct of controlling behavior in broader terms than has been done in many previous studies. Our items also covered inappropriate instructional behaviors that have been proposed to undermine students' sense of autonomy. Whether the level of autonomous behavior mediates the relation between controlling behavior and interest experience will have to be investigated directly in future research.

Moreover, beyond the social interaction aspect of autonomy-supportive climate, we found a distinctive effect of *cognitive autonomy support*. Stefanou et al. (2004) hypothesized that cognitive autonomy support gives students an enhanced sense of control, particularly during engagement with cognitive activities (e.g., problem solving). Cognitive autonomy is supported when the teacher explicitly explains the aim of tasks and activates students' prior knowledge during their implementation. Within SDT, this kind of practice is discussed in terms of the rationale it provides students for grasping and assimilating the value and meaning of an activity, which has been experimentally shown to facilitate more interested engagement with a task (e.g., Deci et al., 1994). That being said, cognitive autonomy differs from a perceived expectation or standard in the classroom to perform well or to learn harder (cf. academic press for understanding, Middleton & Midgley, 2002). Our study provides empirical evidence within actual classroom settings of the engaging effect of cognitive autonomy support as proposed by Stefanou et al. (2004) by demonstrating the effects of cognitive autonomy support over and above those of autonomy-supportive climate and controlling behaviors. Our findings indicate that lessons in which students' prior knowledge and conceptual understanding are activated and the aims of tasks are transparent to students are associated with enjoyment.

Furthermore, the present findings indicate that perceived autonomy support may depend on what teachers say and do in the classroom and that it is less stable than teachers' individual char-

acteristics. Relative to each student's own baseline, some lessons were perceived as more autonomy supportive than others. Therefore, it might be possible to enhance interest in lessons by providing teachers with training in autonomy-supportive teaching (Reeve, 1998).

The consistent findings across the three subject domains indicate that the beneficial effects of autonomy support are quite general and probably apply to other subjects as well. Nevertheless, the significant variation in the effects found among students indicates that some students seem to react more to teachers' autonomy support than others. To understand how autonomy support can benefit different types of students, the underlying processes moderating these effects need to be further investigated.

### *Individual Interest and Interest Experience*

Interest theory predicts that people who have a stable preference for a certain subject domain or content will seek out related activities and that they will enjoy and value opportunities to reengage with relevant contents. As Krapp (2002b; Krapp et al., 1992) argued, individual interest can be conceptualized as a stable person-object relation that, once developed, will influence the quality of further interactions. The present findings clearly show that students' individual interest in a school subject, measured at the beginning of secondary school, significantly predicts their interest experience in the respective lessons over a 3-week period. It is surprising that effects of a similar magnitude were also found for a newly introduced subject (i.e., second foreign language). We had not expected the person-object relation to be as well developed in this context. Whether individual interest in this subject is a function of prior experience outside school or inferred from other related domains (e.g., general interest in foreign language) remains to be investigated.

Our findings indicate that individual interest can be regarded as a motivational resource for students in everyday classroom learning situations (Katz et al., 2006; Sansone et al., 1992). Although lessons may not always coincide with their preferences, and external support may differ from one day to the next, students with higher individual interest in a subject are more likely to have positive learning experiences in the respective lessons. Elementary school grades did not prove to be associated with interest in secondary classrooms. Nevertheless, the association found between individual interest in the subject and interest experience was not perfect. An interest state is rarely triggered by individual interest alone, even when individual interest is very strong (Hidi & Renninger, 2006). A comprehensive account of interest state needs to take other motivational resources and situational factors into account.

### *Toward the Integration of Situational and Individual Factors in Interest Theory*

The present study showed that interest experience as a momentary psychological state is influenced by both situational factors and individual characteristics. Although similar approaches have already been proposed in the interest literature (e.g., Hoffmann, Krapp, & Renninger, 1998), most researchers have investigated either the situational aspect (i.e., situational interest) or the dispositional aspect (i.e., individual interest), meaning that one source of

influence has generally been neglected. For instance, most studies on situational interest have overlooked the influence of individual characteristics (see Schraw & Lehman, 2001, for a review). Working within this framework, it would also be possible to examine the relative importance of other situational factors proposed in the literature with respect to further individual characteristics or motivational resources. Moreover, the interaction between the two sources of influence (e.g., for which persons certain situational factors are effective) could be further investigated.

Broadly speaking, the intraindividual variability observed in interest experience across situations is in line with state-trait theories from personality and social psychology (Eid & Diener, 1999; Steyer, Schmitt, & Eid, 1999), which predict emotion and behavior to have both state and trait aspects. Students' interest and other emotional experiences should be no exception. In fact, much of literature has referred implicitly to the state-trait distinction. It remains for empirical research to examine the magnitude of intraindividual variability in interest across time and situations and to determine whether this intraindividual variability differs across educational environments, phases of interest development, or different trait levels of individual interest.

### Limitations and Future Research

The results of the present study are in line with hypotheses derived from SDT and interest theory, but several empirical limitations warrant discussion. First, the effects of situational factors (e.g., autonomy-supportive climate) established with multilevel analysis are correlational in nature; therefore, inferences cannot be drawn on the causal direction of the effects of the three situational factors on interest experience. For instance, it is possible that teachers pay more attention to students who show interest during the lesson and give them more positive feedback, and thus they are perceived by these students to be autonomy-supportive. Additionally, there is a possibility of third-variable explanations. For instance, external pressures (e.g., impending examinations) may prime negative mood in students (and perhaps also the teacher) and bias both interest experience and the learning situation in a negative direction. To address this limitation, future studies might investigate the effects in a sequence of experimental learning conditions that allow situational factors to be controlled or manipulated.

Second, data on both interest experience and situational factors of the lesson were obtained from students' self-reports. Some relations may therefore be overestimated due to shared method variance. Further research might address this issue by using multiple sources of information (e.g., teacher reports, third-person observations, analysis of instructional tasks) to provide more objective perceptions of instruction (Kunter & Baumert, 2006b).

A third limitation relates to the generalization of the results. Participants in the present study were sampled from the same grade and the same academic track of the three-tier German secondary educational system. To establish their generalizability, the effects observed in the present study need to be replicated in more heterogeneous samples, and at different points in student development. Replication of the present results in samples of different ages and cultural backgrounds would support the claim of self-determination theory that autonomy support is universally beneficial for all individuals.

## Appendix

### Items of the Lesson-Specific Measures

#### *Interest Experience (5 items)*

- I enjoyed the topic.
- It was interesting to me.
- The topic was meaningful to me.
- It was important to me that I thoroughly understood the material covered.
- I saw that the content of the lesson can be useful in real life.

#### *Perceived Autonomy-Supportive Climate (6 items)*

- I felt that my teacher provided me choice and options.
- I felt understood by my teacher.
- My teacher conveyed confidence in my ability to do well in the course.
- My teacher encouraged me to ask questions.
- My teacher listened to how I would like to do things.
- My teacher tried to understand how I see things before suggesting a new approach.

#### *Perceived Controlling Behaviors (4 items)*

- Our teacher expected split-second answers.
- Our teacher's instructions were so vague that nobody knew what to do.
- Our teacher covered so much material that we had difficulty keeping up.
- Our teacher was mean to a student.

#### *Perceived Cognitive Autonomy Support (4 items)*

- We worked through exercises that helped us understand the topic.
- Different students presented their solutions to the same task.
- Our teacher set tasks that required time to reflect.
- Our teacher emphasized the relations between the topics discussed.

# Cognitive Processing About Classroom-Relevant Contexts: Teachers' Attention to and Utilization of Girls' Body Size, Ethnicity, Attractiveness, and Facial Affect

Shirley S. Wang, Teresa A. Treat, and Kelly D. Brownell  
Yale University

This study examines 2 aspects of cognitive processing in person perception—attention and decision making—in classroom-relevant contexts. Teachers completed 2 implicit, performance-based tasks that characterized attention to and utilization of 4 student characteristics of interest: ethnicity, facial affect, body size, and attractiveness. Stimuli were 24 full-body photos of girls that varied along the dimensions of interest. Teachers completed a similarity-ratings task and 4 preference-ratings tasks. Results showed that teachers attended to ethnicity and body size but did not utilize this information when selecting students across contexts. In contrast, teachers relied heavily on affect and attractiveness when making decisions. These results suggest that further investigating cognitive processing in person perception is important in understanding how teachers attend to and use multiple salient student attributes in real-world contexts. This study also illustrates the potential utility of adopting a method that places a premium on internal validity to investigate questions relevant to educational researchers. Future work should investigate how other student information, such as student background or personality, affects teachers' cognitive processing in different classroom-relevant contexts.

*Keywords:* obesity, attractiveness, education, ethnicity, attention

Perception and categorization of people on the basis of salient person attributes is a useful and necessary heuristic for filtering information from complex social stimuli and making sense of the social world (see Fiske, 1993; Macrae & Bodenhausen, 2000, 2001, for a review). McFall's (1982, 1990) social information-processing model provides one way of examining the person-perception process. This framework posits that a series of basic cognitive processes—decoding, decision making, and enactment—operate on the continuous stimulus input received from the environment to produce a behavioral output (i.e., behavior). Understanding the way teachers encode specific student characteristics and utilize those attributes in decision making could better our understanding of teacher behaviors in the classroom. Investigating such basic processes is critical because biased or stigmatizing behavioral output can arise from a combination of biased decoding and decision making based on the input perceived in a specific environment, such as students' salient physical characteristics.

A large body of research on the educational environment has relied on observations of teacher–student interactions in the class-

room (e.g., Blatchford, 2003; O'Connor, Fish, & Yasik, 2004). This work has demonstrated clearly the complexity of teaching and learning in the classroom and has shown that even well-intentioned and subtle teacher behaviors can have unintended negative consequences for students. Our current work builds on such research by attempting to elucidate various cognitive processes that underlie teacher behaviors in the classroom. The many potential facets of student–teacher interactions in real-world situations make it challenging to draw definitive conclusions on the basis of observational methods alone. More standardized and controlled, albeit less externally valid, studies can complement observational research. Studies can help to clarify our interpretation of the observed relationships as well to enhance our understanding of the mechanisms underlying the relationships. Notably, the generalizability of findings from studies that emphasize internal validity can be quite limited, because such studies necessarily control tightly for many important variables to enhance the interpretability of the findings. Thus, one cannot assume that teachers' behavior in experimental settings translates to the real world. The present research employs a compromise between these two research-strategy extremes that integrates strengths of observational and experimental work by systematically examining important teacher, student, and classroom variables in experimental settings that attempt to replicate important aspects of the real-world situation.

The present study examines two aspects of cognitive processing in person perception, attention and decision making, in a contextually meaningful domain—the classroom. Prior to making decisions based on student attributes, teachers must first attend to this information and then choose, consciously or unconsciously, to use that information as a basis for their decisions. We used methodological and analytic paradigms drawn from cognitive science to

investigate how four student attributes—body size, ethnicity, attractiveness, and facial affect—influenced teachers' perceptions of students and teachers' decision making in four common classroom-relevant contexts. We aimed to complement existing observational research in educational psychology by more thoroughly investigating the processes that underlie teachers' observable classroom behavior. The current work focuses on the following three overarching conceptual questions: (a) On what student attributes do teachers focus when not directed to attend to any specific attribute? (b) Does attention to student-specific attributes necessitate the utilization of the information in decision making? (c) Does utilization of student-specific information vary as a function of the decision-making context? Because teachers must make numerous decisions in the classroom in no more than a few seconds, we decided to focus on the process of rapid decision making in this study. However, teachers engage numerous other complex cognitive processes that also are important to student learning. Our examination of such simplified decision-making scenarios is intended to be only a first step toward better understanding the processes underlying teacher behavior, which ultimately may help inform such activities as training new teachers.

Prior research has focused primarily on the processing and use of physical attributes in isolation from one another, such as investigations of perception of either ethnicity or gender, but not both. Few studies have examined individual differences in attention to multiple important person attributes simultaneously. However, in the real world, perceivers must make sense of competing person attributes, each of which conveys information about the individual. In addition, person perception often is assumed to be a traitlike function of the perceiver (e.g., an individual who scores highly on the Modern Racism Scale is more likely to exhibit discriminatory behavior), and the basis for judgments frequently is assumed to be constant across situations. Yet one could imagine that relative utilization of person attributes depends in part on the context, beyond stable individual differences in the utilization of attributes during decision making. This perspective is consistent with the increasing emphasis in educational research on the situational or contextualized nature of teaching and learning (e.g., Barab, Hay, & Yamagata-Lynch, 2001; Barab & Plucker, 2002; Roth, 1998). Similarly, many salient physical attributes, such as body size and attractiveness, covary naturally in the real world (e.g., thinner individuals are viewed as more attractive), and the relative contribution of each attribute to different stages of cognitive processes and overt behavior has rarely been quantified. Finally, the majority of the existing work on processing of ethnicity, attractiveness, and body-size information has utilized explicit self-report measures rather than implicit performance-based measures (e.g., D. F. Chang & Sue, 2003; Langlois et al., 2000). Our focus in this study on performance-based cognitive methods contributes to person-perception research by examining the relative importance of particular person attributes to decision making in standardized but contextually bound situations. Incorporating cognitive-processing methods into studies of person perception may allow researchers to obtain a richer understanding of the cognitive dynamics of teacher behavior in interactions with students.

## Influence of Student Attractiveness, Body Size, and Ethnicity on Teacher Behavior

In educational contexts, teachers' and administrators' perceptions of student attributes often influence their behavior, either implicitly or explicitly. Most research in this area has focused on teacher expectations as determinants of student academic performance, or the Pygmalion effect, in which students whom teachers expect to perform better do, indeed, perform better (Rosenthal & Jacobson, 1966; see Jussim, 1991, for a review). Expectation formation can occur quickly and with little information (Jussim, 1989). In addition, studies on "thin slices" of behavior show that perceptions and evaluations of individuals can form very quickly from limited information (e.g., Ambady, Hallahan, & Conner, 1999; Ambady & Rosenthal, 1992; Borkenau, Mauer, Riemann, Spinath, & Angleitner, 2004; Friedman, DiMatteo, & Mertz, 1980), even in the classroom. For example, Ambady and Rosenthal (1993) found that judges' evaluations of teachers after examining silent video clips as brief as 2 s correlated with students' end-of-semester ratings of these same teachers. Teachers, similarly, readily form expectations of students on the basis of physical characteristics, such as attractiveness, gender, and ethnicity (e.g., Ritts, Patterson, & Tubbs, 1992; Tauber, 1998).

Ethnicity is a critically important variable to study in educational contexts. Educational attainment and achievement of underrepresented minority groups continue to lag behind those of Caucasians at all socioeconomic levels, despite decades of effort to minimize the discrepancy (Education Trust, 2004; U.S. Department of Education, National Center for Education Statistics, 2001). Numerous researchers have examined how teachers' evaluations and expectations of student aggression, ability, and mental health vary as a function of student ethnicity (e.g., D. F. Chang & Sue, 2003; Graham, 1990; Neal, McCray, Webb-Johnson, & Bridgest, 2003). Yet little is known about the relative importance of ethnicity in comparison to other attributes, such as attractiveness or body size, in the classroom. In addition, research in this area often assumes that attention to ethnicity necessitates that the information will be utilized in decision making, without obtaining independent assessments of attention and utilization. Might it be the case that teachers encode ethnicity information but do not use it to make decisions?

An extensive literature shows that attractive children are perceived to be more popular, intelligent, and friendly than less attractive children (e.g., Langlois et al., 2000), and teachers are no exception to these perceptions (see Ritts et al., 1992, for a review). Facial affect has also been found to play a role in student-teacher interactions. A substantial literature points to the importance of understanding nonverbal communication, such as facial expression and posture, on the part of both teachers and students in their interactions in the classroom (e.g., Goldin-Meadow, 2004; Mottet & Richmond, 2000; Tauber, 1998). For instance, Stuhlman and Pianta (2002) interviewed and observed teachers in the classroom and found that negative affect from students was related to greater negative affect from teachers as well as increased behavioral interactions with the teacher. However, affect and attractiveness covary naturally with each other as well as with other variables, such as body size and perhaps socioeconomic status (via the niceness of clothing or grooming). Teasing apart the relative contributions of these naturally covarying or proxy variables is

important to our understanding of the extent to which attractiveness, versus other attributes, influences teachers' cognitive processing.

Another similarly salient physical characteristic, which is associated with traits such as intelligence and friendliness but which has been relatively neglected in previous research, is that of body size (Hebl & Mannix, 2003; Puhl & Brownell, 2001). The attractiveness literature typically treats body size as a control variable by using only head shots as stimuli or by including only normal-weight children in full-body stimulus sets. As a result, little is known about the extent to which teachers attend to and use body-size information independently of attractiveness information when making classroom decisions. Body size is a stigmatized physical attribute that deserves greater exploration in the literature. Being overweight in childhood is associated with a number of negative outcomes, such as social and academic difficulties (Neumark-Sztainer et al., 2002; see Puhl & Brownell, 2001, for a review). Overweight girls complete fewer years of schooling than their average-weight counterparts (Gortmaker, Must, Perrin, Sobol, & Dietz, 1993) and are less likely to receive help in applying to colleges (Benson, Severs, Tatgenhorst, & Loddengaard, 1980). Obese individuals of both genders are less likely to be accepted to college than their nonobese peers, despite equivalent academic performance (Canning & Mayer, 1966). With the rate of childhood obesity skyrocketing—15% of children now are considered obese (Strauss, 2002)—it is increasingly important to understand how teachers process students' body-size information.

The present study extends previous work by examining teachers' attention to and utilization of student-specific attributes in standardized, performance-based assessments and by comparing teachers' relative utilization of important student characteristics, such as attractiveness, body size, and ethnicity, when making rapid decisions. Our study is the first of which we are aware that attempts to tease apart the influences of body size, affect, and attractiveness on teacher attention and decision making. Although literature exists for many stigmatized attributes, these areas of research rarely have been integrated with one another. In this way, the literature fails to reflect the fact that characteristics of the students are multidimensional. This study explores in a standardized manner the process by which certain attributes are attended to over others and how these attributes influence decision making. The paradigms used to examine these cognitive processes differ from what teachers experience in the classroom, which constrains the external validity of our findings. However, these paradigms serve nicely as experimental analogues of one type of information processing that teachers frequently employ in the educational environment—that is, making rapid decisions, ones in which they do not have extensive real time to deliberate, based on limited student information. Teachers' processing of young female students' body size and ethnicity is of particular interest in this study, given overweight and ethnic-minority students' reported academic and social difficulties, as reviewed previously. We anticipated that teachers would attend to students' body size and ethnicity, rely heavily on this information when selecting students in common classroom situations, and show strong preferences for lighter weight and nonminority students.

### Conceptualization and Measurement of Individual Differences in Attention and Decision Making

Similarity- and preference-rating paradigms, well established in the cognitive literature, are used in this study to characterize teachers' attention and decision-making processes in the classroom. These paradigms are used in conjunction with multidimensional scaling (MDS) methods to evaluate individual differences in teachers' attention to particular characteristics of a set of stimuli (e.g., photos, objects, words, descriptions) as well as variability in their utilization of stimulus attributes when making decisions (Bechtel, Tucker, & Chang, 1971; Davison, 1992; Nosofsky, 1992; Treat, McFall, Viken, & Kruschke, 2001; Treat et al., 2002; Viken, Treat, Nosofsky, McFall, & Palmeri, 2002). These paradigms afford performance-based examinations of attention and decision-making processes, in which researchers draw inferences about the operation of participants' cognitive processes by observing their performance on information-processing tasks that necessitate the input of these processes, rather than relying on participants' verbal reports of the operations or products of such processes. These paradigms allow for the assessment of teachers' attention and decision-making processes in a relatively implicit and indirect fashion, as the task instructions neither specify the stimulus attributes of interest nor direct teachers to attend to or use particular child characteristics. Scaling algorithms can be used to quantify individual differences in the extent to which teachers attend to and use the various unspecified child characteristics when completing the similarity- and preference-rating tasks. Additionally, teachers' strategic presentation of their perceptions and judgments are minimized by the use of relatively brief stimulus presentation times (e.g., Fazio & Dunton, 1997). Thus, these relatively implicit, performance-based assessments presumably provide more valid assessments of teachers' cognitive processing in the classroom than more explicit and direct measures, which focus participants' attention on specific student characteristics of interest (e.g., asking participants to rate the extent to which they attend to or use ethnicity or attractiveness to choose between students).

We developed a photo stimulus set of 6- and 7-year-old girls for use in the similarity- and preference-ratings tasks. The final photo set varied significantly along the four dimensions of primary theoretical interest and minimally along other potential dimensions (e.g., clothing and background characteristics). By design, the students depicted in the photos were unknown to the teachers. Thus, all teachers received identical information about the students, and potentially idiosyncratic background knowledge about the students could not influence teachers' judgments. Much previous educational research has used students or photos of students whom the teachers already knew, which introduces numerous alternative explanations for any findings. The use of a standardized stimulus set, rather than a naturally occurring one, also allows the investigator to ensure that there is sufficient variation along each of the dimensions of interest. Our approach allowed us to separate variables that might covary naturally, such as attractiveness and either body size or facial expression, as well as to adequately cover the entire multidimensional space of interest, which facilitated clearer interpretation of the results. Thus, by using a standardized stimulus set and a controlled experimental environment, we could gain a better understanding of the extent to which the teacher calls on Susie Student because of Susie's body size, rather than her attrac-

tiveness or facial expression. Teasing apart the extent to which these naturally covarying attributes affect teachers' perceptions and behaviors supplements existing quasi-experimental research and may shed additional light on our understanding of teachers' decision making in the classroom.

The attributes of primary interest—body size, ethnicity, and attractiveness—were built into the stimulus set. Facial affect was also incorporated because it is a potential indicator of student interest and enthusiasm that is relevant to teachers' decisions (e.g., see Mottet & Richmond, 2000, for a review). It was not possible to represent attractiveness completely independently of body size, ethnicity, and affect in the present stimulus set. Nonetheless, the significant nonoverlap between the attributes raises the possibility that results for attractiveness might diverge from those for the other dimensions. We recognize that teachers likely attend to and use many other child-specific characteristics, such as the child's personality and past behavior or performance. Because the focus of the present study is on understanding how teachers cognitively process students' observable physical characteristics, however, we wanted to rule out competing explanations for teachers processing by eliminating from the stimuli other potential influences on their processing. Other attributes of particular interest could be incorporated readily into the stimulus set in a standardized fashion in future research.

Evaluating Individual Differences in Attention to Stimulus Dimensions

Participants' representation of and attention to stimulus dimensions can be examined within a similarity-ratings paradigm, in

which participants rate the similarity of stimulus pairs on a 10-point scale, where 1 = *not at all similar* and 10 = *extremely similar* (Davison, 1992; Schiffman, Reynolds, & Young, 1981). Participants' similarity ratings provide an indirect indicator of their relative attention to the stimulus dimensions. For example, a participant who judges two happy-looking girls of different ethnicities to be quite similar likely is attending more to affect than to ethnicity. In contrast, a participant who evaluates an attractive pair of heavier and lighter girls as very dissimilar likely is attending more to body size than to attractiveness.

Participants' similarity ratings served as the input for an MDS analysis, which provided a group-level representation of the stimuli or "psychological space" (Davison, 1992; Nosofsky, 1992; Schiffman et al., 1981; Treat et al., 2002). This multidimensional depiction of the stimulus set was spatial in nature: Stimuli that were perceived to be more dissimilar were scaled farther apart than stimuli that were judged to be more similar. Figure 1A depicts a two-dimensional (2-D) psychological space in which each point corresponds to a unique stimulus (i.e., a photo of a particular girl). Stimuli are plotted along the two dimensions spanning the psychological space: body size and affect. This solution indicates that Girl A and Girl B were viewed similarly, whereas both girls were viewed as quite dissimilar to Girl C.

The weighted MDS approach (WMDS; Carroll & Chang, 1970; Carroll & Wish, 1974) simultaneously represents both the group-level psychological space and individual-specific differences in attention to the stimulus dimensions in the group space. Thus, WMDS estimates not only the group-level multidimensional stimulus coordinates but also individual-specific dimensional weights

Figure 1. Group- and individual-level scaling representations of psychological space. Panel A: group-level psychological space for 24 photo stimuli. Panel B: individual-level psychological space for the body-size-oriented individual. Panel C: individual-level psychological space for the affect-oriented individual.

that indicate how much an individual attends to each dimension in the group solution. These dimensional weights are applied to the group-level stimulus coordinates and are assumed to stretch or shrink the dimensions of the group-level psychological space. For example, Figure 1B depicts the individual-specific psychological space of a "body-size-oriented" participant who attends relatively more to body size than to affect, in comparison to the average participant. This orientation is characterized by the stretching of the body size dimension and the shrinking of the affect dimension in the shared psychological space in Figure 1A. Note that this representation scales heavy and light girls further apart than happy and sad girls. Thus, the stretching and shrinking of these two stimulus dimensions represent the participant's perception that heavier and lighter girls are relatively more dissimilar than happier and sadder girls, in comparison to the perceptions of the participant group as a whole. In contrast, Figure 1C portrays an affect-oriented participant who views heavy and light girls as more similar than happy and sad girls.

The present study uses the similarity-ratings paradigm to assess teachers' group-level psychological representation of students as well as individual differences in teachers' attention to the student-specific characteristics of body size, ethnicity, affect, and attractiveness. We anticipate that teachers will attend strongly to students' body size and ethnicity.

### Evaluating Individual Differences in Utilization of and Preferred Directions Along Stimulus Dimensions When Making Rapid Decisions

In addition to exploring teachers' attentional processes, we also seek to understand how teachers utilize information about students when making relatively rapid decisions (i.e., in no more than a few seconds). Teachers often make rapid decisions in the classroom in which they have minimal opportunity to deliberate and limited direction as to the basis for these decisions, such as when selecting a child to answer a question in class. Of course, there are many important classroom situations in which teachers have ample time to deliberate in decision making, such as when awarding student grades. Nonetheless, the constraints under which teachers operate in the classroom necessitate that decisions such as those explored in the present study frequently must be made very quickly. Under these circumstances, teachers do not have time to evaluate consciously and deliberately which student attributes will be the focus

of their attention or will be weighted heavily in their decisions. Thus, we limited stimulus presentation times and urged participants to respond quickly in the present study, in an effort to provide an experimental context that is analogous to that encountered by teachers in the classroom. The pressure to respond quickly also minimizes the influence of social desirability and other presentation biases that come into play as stimulus presentation and decision-making times increase.

Attention and decision making are distinct cognitive processes, as teachers might attend to particular student characteristics but not necessarily use them as a basis for making decisions in the classroom. Given that discrimination against overweight and ethnic minority individuals occurs, however, it appears that many people do use body size and ethnicity as a basis for their decisions. Thus, using the same photo set described previously, we investigate the extent to which teachers use student body size, ethnicity, attractiveness, and affect when making rapid decisions in specific classroom contexts.

The preference-ratings paradigm, in conjunction with the PREFMAP scaling program (Carroll, 1972; J. J. Chang & Carroll, 1972; Meulman, Heiser, & Carroll, 1986), frequently is used to assess individual differences in participants' utilization of the dimensions of a previously specified group-level psychological space; the group-level space typically is obtained from a separate MDS analysis of participants' similarity ratings, as described above. Participants again view stimulus pairs in a preference-ratings task, but they select one of the stimuli rather than rate the similarity of the two stimuli. For example, in one of the preference-ratings tasks in the present study, teachers indicated which of two girls they would call on in class. The summary data that were submitted for PREFMAP analysis consisted of the number of times that each teacher chose each girl.

PREFMAP also calculates individual differences in the preferred direction of the previously specified group-level psychological space. PREFMAP computes individual-specific vectors, which specify the direction that is preferred by an individual in the psychological space. Figure 2A displays sample graphic PREFMAP output for one teacher. Each point again corresponds to a unique stimulus, and the overall stimulus configuration is assumed to be the same group-level psychological space that was uncovered in the similarity-ratings solution depicted in Figure 1A. A teacher's preference data are represented by the arrow that points toward the

Figure 2. Vector model representation of teachers' preferences. Panel A: group-level psychological space and preference vectors for one teacher. Panel B: preference vectors for four teachers.

region of the space that contains the girls she is more likely to choose and away from the region of the space that contains the girls she is less likely to choose. According to the PREFMAP vector model, stimuli that exhibit perpendicular projections to the vector that are closer to the preferred direction are selected with greater frequency than stimuli with perpendicular projections that are farther from the preferred direction. Thus, the teacher in Figure 2A selected heavy, happy girls (e.g., A and B) more frequently and light, unhappy girls (e.g., C and D) less frequently.

We analyze both the signed and the unsigned values of the vector heads in the present study, as they provide different types of information. The absolute values of the vector endpoints indicate individual differences in the utilization of the stimulus dimensions. Figure 2B presents four teachers, each of whom is represented as a normalized vector in this space, and indicates that both Teachers 1 and 3 relied heavily on both body size and affect when making decisions, because their vector endpoints are extreme along both the body size and the affect dimensions. In contrast, Teacher 2 relied almost exclusively on affect when making decisions: The vector endpoint is extreme along the affect dimension and near zero along the body size dimension. Finally, Teacher 4 used neither body size nor affect in her decision making, as the vector endpoints are near zero along both dimensions. Thus, the unsigned vector endpoints for a particular teacher tell us about the teacher's utilization of the stimulus dimensions when making decisions. In contrast, the signed vector endpoints along each dimension indicate individual differences in teachers' preferred directions along the stimulus dimensions. In the present example, focusing on the signed endpoints allows us to distinguish Teachers 1 and 3, who both relied heavily on body size and affect when making decisions but who selected heavy, happy and light, unhappy girls, respectively.

The preference-ratings paradigm is used in the current study to examine teachers' use of girls' body size, ethnicity, affect, and attractiveness when making rapid decisions in four classroom-relevant contexts. Context selection was informed by the literature on stereotyping based on ethnicity, attractiveness, and body size (Puhl & Brownell, 2001; Ritts et al., 1992; Zebrowitz, Hall, Murphy, & Rhodes, 2002) as well as informal discussions with numerous teachers about the kinds of rapid decisions they make routinely in the classroom. We designed and selected contexts in which it seemed likely that teachers would use the dimensions of interest to us in this study. Teachers in this study also were asked to imagine that they were substitutes who did not know these students, as this provided a plausible rationale for making decisions about students with whom they were unfamiliar. We recognize that there are numerous other classroom-relevant contexts and teacher roles that we could have examined. Given our focus on understanding the underlying processes of how teachers use specific student information to inform their decisions, however, we chose to design a tightly controlled study, despite its limited generalizability. Future research can and should examine teachers' perceptions and behaviors in other contexts involving different cognitive processes, such as situations that call for more deliberate and time-consuming decision making.

In the current work, one context required a teacher decision that conveyed beliefs about students' perceived abilities (i.e., selecting a student to complete a difficult problem on the board). Another required a decision that communicated teacher perceptions of the

student's responsibility or dependability (i.e., asking a student to take a note down the hall). A third context required a teacher decision that potentially resulted in special attention or encouragement for a student (i.e., calling on a student to answer a question). The final context targeted a teacher decision that conveyed who the teacher felt would like or deserve special attention (i.e., assigning the lead role in a class skit), which we chose specifically because we hypothesized that physical appearance would be a factor in the teachers' decision making.

## Present Study

The present study aimed to characterize three aspects of teachers' cognitive processing in the classroom that have not been explored previously: (a) teachers' relative attention to young girls' body size, ethnicity, attractiveness, and facial affect; (b) teachers' relative utilization of these characteristics when selecting girls in four commonly occurring classroom contexts; and (c) teachers' preferred directions along these dimensions when selecting girls in the four contexts. Additionally, we explored the link between individual differences in these cognitive variables and teachers' self-reported teaching experiences and demographic information. Given the marked social and academic difficulties reported by heavier and ethnic minority students, we anticipated that teachers would (a) attend strongly to body-size and ethnicity information in the similarity-rating task; (b) utilize body-size and ethnicity information heavily when selecting children in the preference-rating tasks; and (c) exhibit a preference for lighter, nonminority children in the preference-rating tasks.

## Method

### Participants

Twenty-seven elementary school teachers (21 women, 6 men) from nine different schools within a local school district participated in the study; they were predominantly Caucasian (24 Caucasians, 1 Latina, and 2 Asian Americans). Their mean age was 36.8 years ( $SD = 12.1$ ), and they reported an average of 10.2 years ( $SD = 9.2$ ) of teaching experience. Participants were informed of the study at their monthly staff meeting and by subsequent individual contact at lunch or after school. They were invited to participate in the study during nonschool hours in exchange for \$20 or a book donation to their classroom.

### Development of Experimental Stimuli

Twenty-six 6- and 7-year-old female models were recruited from an elementary school outside the district in which the study was conducted for development of the stimulus set. Written parental permission and verbal child assent were obtained for each child. Each model was photographed individually with standard lighting while standing and facing the camera at the same fixed distance. All models were asked to wear plain white T-shirts, blue jeans, and light-colored sneakers to minimize variability along dimensions that were irrelevant to the study. Models were asked to vary their facial expression across photographs (e.g., look happy, look sad, and look "neutral"). The stimulus set was quite ethnically diverse; 10 of the 26 models were African American or Asian American. Multiple photos of each child were taken, which pro-

vided us with a large number of photos from which to select a stimulus set that varied sufficiently along the dimensions of interest.

To enhance the variability along the body-size dimension, we digitally altered the photos using the WinMorph program (Kumar, 2002) to increase and decrease the original body size of the models. Only body size was warped; faces and facial expressions remained untouched. Each model was warped to appear both heavier and lighter than her current body size so that there were nine possible combinations of body size and affect for each model (happy, sad, and neutral affect crossed with actual, thinner, or heavier body size).

*Normative data collection.* Normative data were collected to quantify the stimulus values along each dimension and to ensure that the dimensions of interest in the stimulus set varied sufficiently and as independently as possible. Data were collected on those photos that did not appear grossly unrealistic or inappropriate to the experimenter (e.g., facial expression was incongruent with the desired expression).

Twenty-seven undergraduate women rated 140 photos along four 10-point scales for the following attributes: body size (1 = *light*, 10 = *heavy*), affect (1 = *unhappy*, 10 = *happy*), friendliness (1 = *unfriendly*, 10 = *friendly*), and attractiveness (1 = *unattractive*, 10 = *attractive*). Participants also rated the perceived ethnicity of the models using any possible combination of five racial groups (Asian, Hispanic, African American, Caucasian, and Native American), the age of the model (4 to 13 years old), and whether the photo looked realistic (i.e., yes or no). Photos were presented in a random order. Participants were instructed to respond as quickly as possible, because we were interested only in their first impressions, and they were told that there were no right or wrong answers.

*Stimulus set selection.* The final stimulus set included 24 photos of unique girls. Stimulus selection was based on the normative data and subject to several constraints. Stimuli were selected to cover the entire 2-D Body Size  $\times$  Affect space as completely as possible.<sup>1</sup> Girls of different ethnicities were distributed proportionally across this space. The judged realism of the stimuli also was taken into account in the selection process; we eliminated those photos that raters deemed unrealistic.

Stimuli also were selected such that the dimensions of primary interest varied as independently as possible. Affect and body size were uncorrelated, as intended, Pearson<sup>2</sup>  $r(24) = -.004$ . Friendliness and affect correlated nearly perfectly,  $r(24) = .988$ ,  $p < .01$ ; we focused only on the affect dimension in pilot testing and actual testing procedures. Attractiveness correlated with both affect and body size,  $r(24) = .599$ , and  $r(24) = -.421$ , respectively, although these correlations were minimized to the extent possible during the stimulus selection process. Age did not correlate significantly with any of the attributes.

## Cognitive Tasks

*Similarity-ratings task.* Participants viewed multiple pairs of stimuli on a laptop computer and rated their similarity on a 10-point scale (1 = *not at all similar*, 10 = *extremely similar*). Participants viewed a random subset of 100 of the 276—that is,  $(24 \times 23)/2$ —pairwise stimulus combinations. They were asked to respond as quickly as possible and were told that we were inter-

ested only in their first impressions and that there were no right or wrong answers. Each stimulus pair was also presented for only five seconds to encourage participants to respond more rapidly and to avoid lengthy deliberation about their responses.

Eight undergraduate students completed a pilot version of the similarity-ratings task for credit in their introductory psychology class. This pilot work ensured the following: (a) Ethnicity, body size, and affect emerged as dimensions in the psychological space; (b) the stimulus set adequately covered the psychological space; (c) the dimensions varied as independently as possible; and (d) the MDS solution based on the first 100 trials was nearly identical to the solution yielded from all trials.<sup>3</sup>

*Preference-rating task.* Participants were asked to assume that they were substitute teachers for the day and had never seen this group of students (i.e., the stimulus set) before. Participants viewed all 276 possible pairs of stimuli for 2 s apiece<sup>4</sup> and, for each pair, selected one of the two displayed stimuli. The presentation time was established on the basis of previous research and practical considerations. Social perception research has found that behavioral snapshots as brief as 2 s yield meaningful information for making evaluations (e.g., Ambady & Rosenthal, 1993; Friedman et al., 1980) and that longer observations do not lead to more accurate prediction of social outcomes (see Ambady & Rosenthal, 1992, for a review). Information processing related to person perception also often uses photo stimuli, and these stimuli are commonly presented for periods of time similar to the duration in which the stimuli in the current study were presented (e.g., Cloutier, Mason, & Macrae, 2005; Macrae, Quinn, Mason, & Quadflieg, 2005; Michel, Caldara, & Rossion, 2006). Given the number of trials that participants would have to complete, it also was important to select the briefest significant presentation time possible to decrease participant fatigue while ascertaining meaningful data. Thus, using the social perception literature and practical considerations as guides, we selected 2 s as the presentation duration in this task. This relatively brief presentation time also maximized similarity to the short time scale on which teachers necessarily make such decisions in classroom contexts.

Four independent decision-making contexts were presented to participants in a counterbalanced order:

1. You ask a question in class. These two students raise their hands at the exact same time. They both speak a

<sup>1</sup> The affect dimension was adequately represented by girls with neutral and happy expressions, as stimuli with neutral expressions were perceived as very unhappy. Thus, it was unnecessary to include stimuli with sad expressions in the stimulus set.

<sup>2</sup> All correlations reported in the text are Pearson correlations, unless otherwise indicated.

<sup>3</sup> Pilot data showed that the MDS solutions based on 100 trials were nearly identical to those estimated from the full 276 trials. Thus, participants in the primary study were asked to rate only 100 pairs in the interest of minimizing participant fatigue.

<sup>4</sup> We conducted pilot work to examine whether it was feasible for participants to complete the ratings within this short time frame. The data analyses yielded readily interpretable and adequately fitting multidimensional solutions, indicating that participants were able to complete the task within this time frame.

similar amount in class. Who do you call on to give the answer?

2. You need a student to take a note to the principal's office all the way on the other side of the building. Who do you ask?
3. Two students are going to the board to complete a problem in front of the class. One problem is easier and one is hard. Who do you assign to do the hard problem?
4. Each reading group in the class acts out a short story for the others on Fridays. The roles are assigned two days prior, and today is "casting day." Each student is assigned a role, but the "leading lady" is assigned first. Who do you choose to play this part?

Twenty-four undergraduate students completed a pilot version of the four preference-rating tasks for credit in their introductory psychology class. This pilot work demonstrated that the task was feasible under speeded conditions and that participants utilized the stimulus dimensions when making decisions in the four contexts.

### *Self-Report Measures*

All participants completed a questionnaire that assessed demographic information, teaching-relevant information, and their evaluation of the cognitive tasks. Teaching information included years of teaching experience, amount of experience with a diverse student body (e.g., gender, ethnicity, socioeconomic status, and body size), current satisfaction with teaching experience (1 = *not at all satisfied*, 7 = *completely satisfied*), and intention to continue teaching (1 = *do not intend to continue teaching*, 7 = *definitely intend to continue teaching*).

The cognitive-task evaluation consisted of three components: (a) a written description of the student characteristics that teachers used to make decisions in each of the four decision-making contexts; (b) a written description of what additional information they would use in the real world when making similar types of decisions; and (c) a checklist of child characteristics that the teacher deliberately attempted not to use in the preference-rating tasks, including hair color, body weight, height, style of clothing, ethnicity, facial expression, body posture, and hair style.

### *Procedure*

Participants provided informed consent and then completed the similarity-ratings task and the four preference-ratings tasks on a laptop computer. Instructions urged participants to complete the tasks as quickly as possible, as we were interested in their first impressions and there were no right or wrong answers to the questions. We purposely did not direct participants to attend to any of the stimulus dimensions of interest. Finally, participants completed the self-report measures. They were debriefed and paid after completing the experimental tasks.

### *Data Screening*

All data were checked for missing values and possible outliers. Although the distributions of several demographic variables were

skewed, there were no obvious outliers, and thus all data were retained for analysis. Nonparametric analyses were conducted with nonnormally distributed variables. Normality of proximity indexes is not assumed in MDS analyses; therefore, all similarity-ratings and preference data were retained.

## **Results**

### *WMDS Analysis of Dimensional Attention*

*Analysis specifications.* Participants rated the similarity of 100 randomly presented pairs of photos out of a total of 276 possible photo pairs. WMDS was used to characterize the group-level psychological space as well as individual differences in teachers' attention to stimulus dimensions. Similarity ratings were reverse coded prior to analysis (i.e., 10 = 1, 9 = 2, etc.), because WMDS analyzes dissimilarity ratings (Carroll & Chang, 1970; Carroll & Wish, 1974). After recoding, a dissimilarity matrix of the input data was created for each participant; missing data (i.e., 176 ratings per participant) were ignored. Equal dissimilarity values, or "ties" in the data, were "untied," or not constrained to be equal in the analysis. Nonmetric MDS analyses of the 27 resulting matrices estimated both group-level stimulus coordinates and individual-specific dimension weights in two, three, four, and five dimensions.<sup>5</sup> All participants' data were retained, as fit indexes were adequate for all individual participants across all four solutions.

*Selecting solution dimensionality.* We determined the dimensionality of the selected solution by examining the relative fit of the models, the interpretability of the estimated dimensions, and the consistency of the obtained dimensions with the dimensions of theoretical interest. The primary indicator of model was the stress index, a badness-of-fit index that ranges between 0 and 1. Stress quantifies the magnitude of the deviation of the scaled distances from an ordinal transformation of participants' similarity ratings (Davison, 1992; Schiffman et al., 1981). Stress values for the 2-, 3-, 4-, and 5-D solutions were .192, .133, .104, and .088, respectively.<sup>6</sup> The magnitude of the fit indexes was comparable to that reported in other scaling studies of complex social perception (e.g., Treat et al., 2001, 2002). The relative improvement associated with an increase in dimensionality was greatest in the move from a 2-D to a 3-D solution (.059), but modest improvement also was noted for the 4-D solution relative to the 3-D solution (.029). However, both visual inspection of the solution and the results of the correlational analyses described below suggested the superiority of the 4-D solution, which accounted for 85.9% of the variability in participants' similarity ratings.

<sup>5</sup> Nonmetric MDS assumes only an ordinal relationship, rather than a linear relationship, between participants' proximity ratings for stimulus pairs and the scaled distances between stimuli in the MDS solution. Thus, only the rank ordering of participants' similarity ratings is assumed to be meaningful.

<sup>6</sup> The fit of the WMDS model varies not only as a function of the number of retained dimensions but also as a function of the number of stimuli and the number of participants. Moreover, model fit is expected to be worse when perceptually and conceptually complex stimuli are being evaluated, as in the present study. Thus, fit adequacy is best evaluated on a study-by-study basis by ascertaining whether the obtained stress values are decidedly lower than those observed when comparable random data matrices are evaluated (see Treat et al., 2001, for an illustration of this).

*Interpreting solution dimensions.* To characterize the dimensions of the selected 4-D solution, we correlated the 4-D stimulus coordinates with the normative data for body size, affect, and attractiveness. Affect correlated most strongly with the fourth dimension (Pearson  $r = -.59$ ), while body size correlated most strongly with the third dimension ( $r = .91$ ). Attractiveness showed moderate associations with both the first and the third dimensions ( $r_s = -.47$  and  $-.41$ , respectively).

Visual inspection of the psychological space suggested that the first two dimensions in the WMDS solution represented variation in the girls' ethnicity, as girls with similar ethnicities were scaled more closely to one another than girls with different ethnicities. As illustrated in Figure 3, this 2-D representation of the girls' ethnicities was more interpretable as four clusters than as two continuous dimensions. The four clusters contained the 5 African American girls, the 4 Asian American girls, the 5 dark-haired Caucasian girls, and the 10 light-haired Caucasian girls.

In summary, our analyses suggest that the first two dimensions in the WMDS solution represented variability in ethnicity, whereas the third and fourth dimensions represented variation in body size and affect, respectively. Attractiveness clearly was relevant to participants' similarity ratings but did not emerge as a separate fifth dimension in the WMDS analyses. Thus, we did not evaluate individual differences in attention to attractiveness.

*Individual differences in dimensional attention.* We depicted individual differences in attention by allowing dimensions to be weighted between 0.0 and 1.0 for each individual, such that a higher weight indicated greater attention to that dimension. Figure

4 depicts the average dimensional attention weights for the 27 teachers in two 2-D scatterplots. The average dimensional attention weights were similar for the four dimensions: .49, .45, .44, and .41 for Ethnicity 1, Ethnicity 2, body size, and affect, respectively. The similarity of the magnitude of these attention weights indicated that the average participant attended at a similar level to all four dimensions (i.e., the perceived salience of the four dimensions represented in this stimulus set was roughly equivalent). Substantial individual variation in participants' dimensional attention also emerged, particularly for the Ethnicity 1 and body-size dimensions, as indicated by greater standard deviations in the weights for these two dimensions ( $SDs = 0.15$  and  $0.16$ , respectively) than for the Ethnicity 2 and affect dimensions ( $SDs = 0.08$  and  $0.10$ , respectively). Overall, therefore, participants on average clearly were attending to the girls' body size, ethnicity, and affect.

Individual differences in dimensional attentional patterns were unrelated to teachers' age, years of teaching experience, job satisfaction, or amount of experience in working with students of diverse backgrounds. Nonparametric (Spearman's) correlations between attentional subject weights and individual-differences variables were uniformly small and no more frequently significant than would be expected by chance alone. For example, teachers who reported having a large percentage of African American or Asian American students in their classrooms in the last 5 years did not attend more or less to ethnicity than teachers who reported little experience with ethnic minorities. Moreover, teachers who reported avoiding the use of certain student characteristics did not differ in their attention to dimensions compared to teachers who

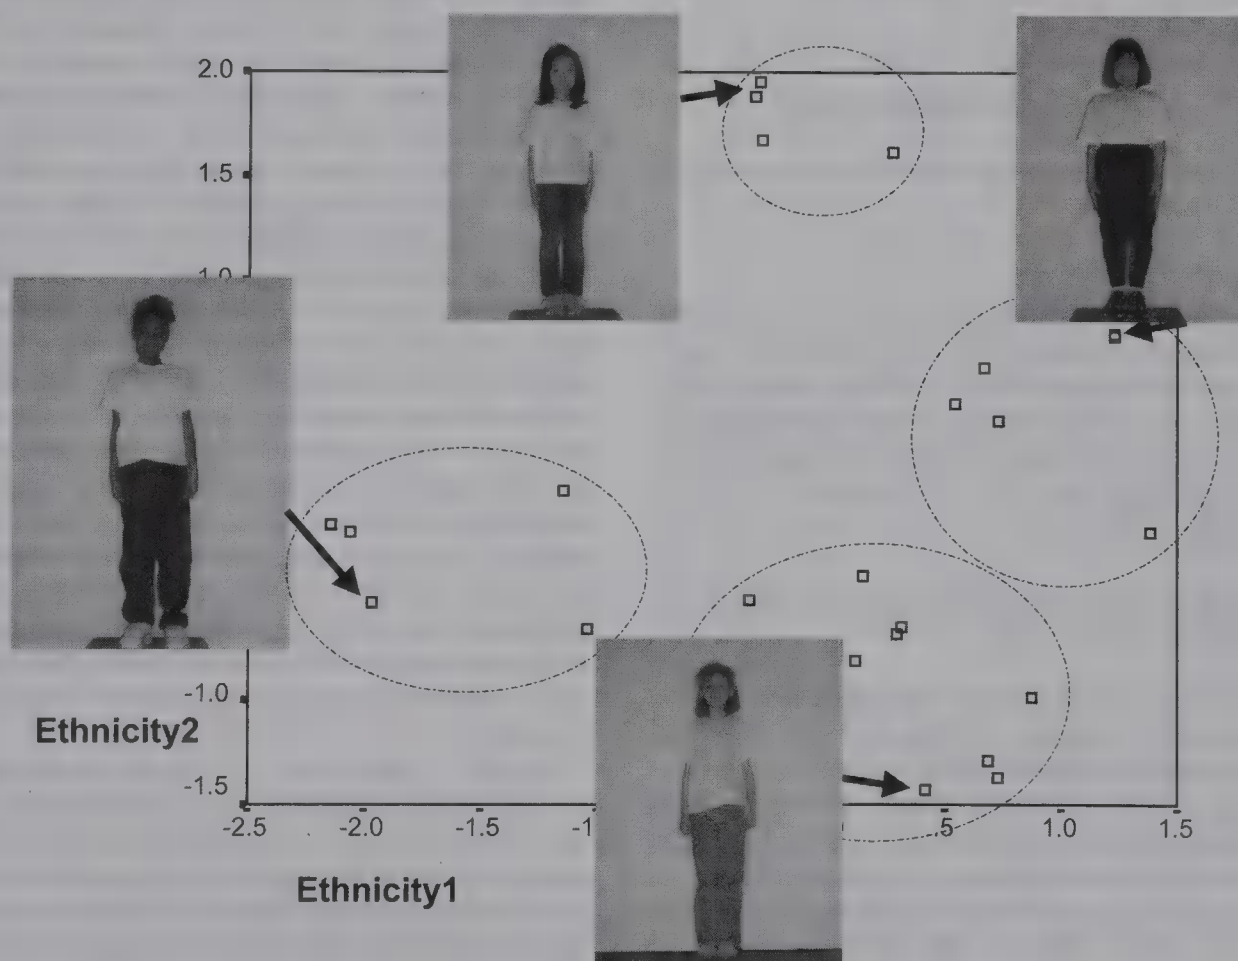

Figure 3. Two-dimensional scaling representation of ethnicity.

Figure 4. Dimensional attention weights for four-dimensional weighted multidimensional scaling solution.

did not report avoiding the use of characteristics. For instance, the 16 teachers who reported avoiding body size did not attend less to body size than the 10 teachers who did not report avoiding body size. These results suggest that there were substantial individual differences in attention to the student attributes of interest—body size, affect, and ethnicity—that were not associated with basic teacher demographic information.

#### *PREFMAP Analysis of Dimensional Utilization and Preferred Dimensional Directions*

Participants viewed all 276 pairwise combinations of the 24 girls and selected 1 of each pair of girls in each of the four decision-making contexts. The PREFMAP-3 program (Meulman et al., 1986) was used to quantify individual differences in the utilization of and preferred directions along the stimulus dimensions in the four decision-making contexts. To prepare the data for analysis, we totalled the number of times each girl was selected separately for each teacher and context; the resulting values ranged from 0 to 23 selections for the 24 girls in each of the four contexts. Then we created a Participant  $\times$  Stimulus ( $27 \times 24$ ) matrix of

these counts for each of the four contexts. These matrices served as the input data for four separate PREFMAP analyses.

For each of the four contexts, we conducted a 5-D, external, nonmetric PREFMAP analysis (Meulman et al., 1986). In external analyses, the stimulus coordinates are constrained to be equal to relevant values external to the choice data. The “external” approach to preference analysis eliminates the need to estimate both stimulus coordinates and vector endpoints in a single analysis, as the stimulus coordinate estimates are fixed, rather than free, parameter estimates. The resulting reduction in the number of estimated parameters reduces the likelihood of problematic solutions, such as multiple solutions that fit equally well but provide markedly different parameter estimates (Borg & Groenen, 1997; Davison, 1992; Schiffman et al., 1981). Such problems commonly arise when “internal” approaches to preference analysis are used, because so many parameters are being estimated (i.e., the model is far too complex to fit to the available data). Thus, in the present case, only 27 vector endpoints were estimated (i.e., five parameters were estimated per teacher). Stimulus coordinates were derived from two external sources in our analyses: (a) the WMDS solution, which provided stimulus coordinates for body size, affect, and the two dimensions of ethnicity, and (b) the standardized normative ratings for attractiveness. Attractiveness was included in the PREFMAP analyses to facilitate evaluation of teachers’ relative utilization of body size and attractiveness. Ties in the preference data were untied in the analyses.

In the nonmetric approach to preference scaling, PREFMAP-3 selects parameter estimates that maximize the correlation between an ordinal (rather than linear) transformation of participants’ preference data and the model-predicted preferences (Meulman et al., 1986). This goodness-of-fit index was highest for the first context ( $r = .829$ ) and was similar for the remaining three contexts ( $r_s = .755, .750, \text{ and } .788$ , respectively). These values indicated that the five dimensions accounted for a substantial proportion of the variability in participants’ choice data across the four decision-making contexts. Here again, the fit of the model to randomly generated data was markedly worse.

We normalized teacher-specific vectors within teacher to be of unit length across the five imposed dimensions prior to conducting further analyses (i.e., the square root of the sum of the squared endpoint values equaled 1.0). Thus, the absolute values of the five vector endpoints ranged from a minimum of 0.0, which indicated no utilization of a dimension, to 1.0, which indicated sole utilization of a dimension. Normalization of vector length maximized the comparability of the vector endpoint values across teachers, as the length of unnormalized vectors in the PREFMAP model varied as a function of the fit of the model to each teacher’s choice data. Parallel analyses of the unnormalized vector data resulted in identical conclusions, so we present the findings based on the normalized vector data in the following section to maximize their interpretability.

*Analysis of dimensional utilization.* The unsigned values of the vector endpoints indicated teachers’ dimensional utilization of the five dimensions but not the preferred direction along the dimension. For example, these values indicated whether body size was important to a teacher’s decisions but not whether the teacher typically tended to select heavier or lighter girls.

Figure 5 presents average utilization values for the five attributes across the four decision-making contexts. A 5 (attribute)  $\times$

Figure 5. Average dimensional utilization of five attributes in four contexts. Vertical rules depict standard errors of the means.

4 (context) repeated-measures ANOVA indicated a main effect of attribute,  $F(4, 104) = 16.536, p < .001$ , on dimensional utilization. Neither the context effect nor the Attribute  $\times$  Context interaction was significant. Post hoc examination of the attribute effect, using Sidak-based multiple comparisons, indicated that (a) teachers used affect and attractiveness (utilization  $M_s = 0.526$  and  $0.457$ , respectively) significantly more across contexts than the body size, Ethnicity 1, or Ethnicity 2 dimensions ( $M_s = 0.321, 0.296$ , and  $0.212$ , respectively;  $p_s < .05$ ) and (b) teachers used body size significantly more than the Ethnicity 1 dimension ( $p < .05$ ). Minimal individual differences were present in teachers' utilization of the Ethnicity 1, Ethnicity 2, and body size dimensions ( $SD_s = 0.110, 0.113$ , and  $0.122$ , respectively), whereas variability in utilization of affect and attractiveness was greater ( $SD_s = 0.193$  and  $.179$ , respectively) and potentially predictable in later analyses.

Figure 6 presents the PREFMAP representation of teachers' decision making in a representative context, the "principal note" context. The 27 vectors specify the 27 teachers' preferred directions along each of the five dimensions. The figure illustrates teachers' greater utilization of affect and attractiveness (bottom panel), relative to the remaining three attributes, when selecting a student to take a note to the principal's office. In other words, the length of the typical teacher's vector was substantially longer along the affect and attractiveness dimensions than along the remaining three dimensions.

**Analysis of preferred dimensional directions.** The signed values of teachers' vector endpoints indicated their preferred direction along the five dimensions (e.g., whether a teacher tended to choose happy or sad girls). Figure 7 displays the average signed values along the five dimensions for the four decision-making contexts. A 5 (attribute)  $\times$  4 (context) repeated-measures ANOVA indicated effects of both attribute,  $F(4, 104) = 6.472, p < .001$ , and context,

$F(3, 78) = 3.000, p < .05$ . The Attribute  $\times$  Context interaction was not significant. Sidak post hoc evaluations of the attribute effect revealed that the preferred direction along the affect dimension was significantly more positive (i.e., happy) than the preferred directions along body-size and both ethnicity dimensions (all  $p_s < .05$ ) and that the preferred direction along the attractiveness dimension was significantly more positive (i.e., attractive) than the preferred directions along the Ethnicity 1 and body-size dimensions (both  $p_s < .05$ ). In other words, happy, attractive children were more likely to be selected across the four contexts than children of a particular body size or ethnicity. These findings are readily discerned from a reinspection of teachers' preferred directions along the five dimensions in Figure 6. That is, the majority of the vector heads point toward the positive ends along the affect and attractiveness dimensions; few vectors point toward the sad-unattractive quadrant of the space. Post hoc evaluations of the significant context effect indicated that the preferred direction was significantly more positive across dimensions in the first context than in the second context ( $p < .05$ ); this finding simply reflects the greater consensus of teachers' preferred directions along the five dimensions in the first decision-making context (i.e., teachers were much more likely to select attractive, happy girls in the first context).

We supplemented this quantitative analysis of teachers' preferred directions along the five stimulus dimensions with a more qualitative characterization of the data for two reasons. First, the preferred direction along a particular dimension only matters substantively to the extent that a teacher utilizes this dimension significantly when making decisions. In other words, showing a slight preference for lighter children when one's decisions are determined almost entirely by children's affect or attractiveness is of limited concern in the present context. Second, marked disagreement among teachers about the preferred direction along a

Figure 6. PREFMAP representation of 27 teachers' decision making in the "principal note" context.

dimension could result in a mean signed value of zero. Thus, Table 1 summarizes the preferred directions of the 27 teachers who showed a strong preference for any of the five dimensions in each of the four contexts; a strong preference was indicated by an average utilization value greater than or equal to .50 for a dimension. As demonstrated in the prior analysis of the utilization data, far more teachers utilized affect and attractiveness than the remaining three dimensions. This supplemental analysis reveals that

teachers who utilized these dimensions strongly in their decision making showed a marked preference for happy and attractive girls. Chi-square analyses demonstrated that the preferred direction varied significantly for both the affect and the attractiveness dimensions when collapsed across context,  $\chi^2(1, N = 27) = 23.113$  and 17.894, respectively,  $ps < .05$ . In contrast, teachers who utilized the remaining three dimensions did not show a significant directional preference, although our power to detect directional preferences was quite small for these three attributes, given their limited utilization.

*Individual differences in dimensional utilization and preferred directions.* Nonparametric correlational methods were used to examine individual differences in dimensional utilization and preferred directions. Neither dimensional utilization nor the preferred directions along those dimensions were related to teachers' age, years of teaching experience, teacher satisfaction, and amount of experience with students of diverse backgrounds. In addition, teachers who reported avoiding the use of student characteristics did not utilize these characteristics significantly less than teachers who did not report such avoidance. One-tailed  $t$  tests were used to evaluate whether teachers who reported avoiding body size or ethnicity when making decisions actually used body size or ethnicity significantly less than the remaining teachers. No evaluations were significant. In fact, the average effect size (Cohen's  $d$ ) across the four contexts for utilization of body size by teachers who did and did not report avoiding body size was  $-0.67$ , opposite of the predicted direction of the effect, indicating that teachers who reported avoiding body size actually were more likely to use it. Across the four contexts, utilization of body size correlated with avoidance of using body size .22, .10,  $-.07$ , and .23, with positive correlations indicating that teachers who reported avoiding body size actually used body size information more in decision making. Correlations between avoidance of ethnicity information and use of ethnicity in decision making were similar in magnitude and direction. The average effect sizes comparing the utilization of ethnicity for teachers who did and did not report avoiding the use of ethnicity were .09 and .03 for the first and second ethnicity dimensions, respectively, across the four decision-making contexts. Overall, these findings suggest that teachers were unsuccessful in modifying their decision making in accordance with their desires to avoid use of ethnicity and body size, presumably in part because of the relatively brief stimulus presentation times and the urging to respond quickly.

## Discussion

Previous research suggests that overweight children and some ethnic minority students struggle both socially and academically in school, but few studies have considered the role of teachers' cognitive processing of students' attributes as potential correlates of these difficulties (Puhl & Brownell, 2001, 2004; U.S. Department of Education, National Center for Educational Statistics, 2001). The purpose of this study was to examine two aspects of cognitive processing of person attributes in classroom-relevant contexts—attention and decision making—by investigating teachers' perception of students across multiple stigmatized attributes. We examined teachers' relative attention to competing student-specific characteristics and teachers' utilization of and preference for student characteristics when making different decisions in

Figure 7. Average preferred directions for five attributes in four contexts. Vertical rules depict standard errors of the means.

classroom-relevant contexts. The student characteristics of particular interest to us in the study were a subset of those found previously to be associated with student performance or teacher judgments—ethnicity, attractiveness, affect, and body size—but had not been investigated relative to one another. Our study emphasized internal validity at the cost of external validity, allowing us to examine the independent impact of these attributes, which often covary under naturally occurring conditions, on teachers' cognitive processing in specific decision-making contexts. Isolating a subset of dimensions of interest also ensured that we had ruled out the influence of other potential covariates of these dimensions (e.g., students' personality, background information) on teachers' processing in these contexts. We recognize that there are many differences between the situations in the study and those that occur in the classroom and that the research program increas-

ingly needs to include stimulus features that make the situations as real as possible. Such standardized situations and stimuli were necessary in this initial study, however, to parse out the extent to which teachers were processing specific student information in classroom-relevant contexts involving rapid decision making. We hypothesized that teachers would show substantial attention to and utilization of students' body size and ethnicity and would exhibit preferences for lighter, nonminority students.

#### Teacher Attention to Student Characteristics

WMDS analysis of the similarity-rating data revealed that teachers attended, as expected, to four interpretable, underlying dimensions that corresponded to the dimensions we built into the stimulus set: body size, ethnicity (two dimensions), and affect. As a

Number of Teachers Showing Strong Preferred Directions for the Five Attributes in the Four Decision-Making Contexts

Attribute	Endpoint	Context				Total
		1	2	3	4	
Ethnicity 1	+ values	1	3	1	0	5
	– values	0	2	1	1	4
Ethnicity 2	+ values	1	2	3	0	6
	– values	0	3	3	2	8
Body size	Heavy	4	3	4	3	14
	Light	1	5	4	1	11
Affect	Happy	16	10	11	7	44
	Sad	3	0	0	6	9
Attractiveness	High	10	8	8	12	38
	Low	2	2	2	3	9

Note. Average dimensional utilization was greater than .50. Context 1 refers to selection of a student who asks a question in class, Context 2 refers to choosing a student to take a note to the principal's office, Context 3 refers to selecting a student to solve a difficult math problem, and Context 4 involves choosing a student to be the leading lady in a classroom skit.

group, participants attended to these dimensions at similar levels, which indicates that the dimensions were perceived to be of similar salience in this particular stimulus set. Attractiveness did not emerge as an independent underlying dimension but correlated moderately with two other dimensions in the WMDS solution. Substantial individual differences in teacher attention to different dimensions emerged, particularly with respect to body size and one of the ethnicity dimensions. Variability in teachers' attentional patterns did not correlate with the individual-differences variables that we assessed, however, such as teacher demographic information and teaching experience with diverse groups of students. Other individual-differences variables, such as teacher ethnicity or body size, could not be examined as moderators of teachers' attention or utilization patterns because of the restricted range of variation but are important to examine in future research.

The use of MDS techniques allowed us to map teachers' perceptual representations of complex person attributes, such as ethnicity. Rather than assuming that ethnicity was perceived as varying continuously along a single dimension, we conducted MDS analyses that indicated that teachers' perceptions of ethnicity were best represented nominally along two dimensions. Girls from different ethnic groups were perceived as belonging to one of three fairly distinct clusters: Asian American, African American, and Caucasian. Dark-haired Caucasian or possibly Hispanic stimuli served as "transition" stimuli between the groups. These results raise questions for future research in terms of how ethnicity is perceived and how its perception might differ as a function of the individuals' own ethnicity and the social context in which the perceiver exists. Implicit, performance-based measures may allow us to capture more accurately how individuals perceive such complex person attributes under specific conditions of interest.

### *Teacher Utilization of Student Characteristics in Decision Making*

Given the documented academic and social difficulties of overweight and ethnic-minority students, we hypothesized that teachers would rely heavily on students' body size and ethnicity when selecting students in four contexts that teachers had deemed classroom relevant: choosing a student to call on in class, selecting a student to take a note to the principal's office, assigning a student to complete a difficult math problem on the board, and picking a student to take a leading-lady role in a class skit. Although the length of time that stimuli were presented may seem brief, teachers routinely make similar rapid decisions in the classroom, and the scaling analyses indicated that teachers systematically used multidimensional student information to make decisions in the preference-ratings task. Unexpectedly, PREFMAP analyses of teachers' choice data indicated that teachers relied predominantly on girls' affect and attractiveness in these decision-making contexts and used ethnicity and body size to a much more limited extent. Despite the moderate correlation between attractiveness and body size, a different pattern of findings emerged for teacher utilization of girls' body size versus attractiveness. Thus, it appears that teachers attended to but did not utilize body-size and ethnicity information when making decisions in classroom contexts. We need to conduct future work to better understand the extent to which the decisions made under these highly controlled conditions converge with decision making in actual classroom contexts.

Teachers' surprisingly infrequent use of body-size and ethnicity information warrants further investigation. Their efforts to present themselves in a favorable light provide a poor account of this finding; the tasks were speeded and required teachers to make over 1,000 choices between pairs of complex multidimensional stimuli, which presumably decreased the likelihood that participants would or could avoid the use of body size or ethnicity when making decisions. Additionally, teachers who reported attempting not to use this information nonetheless used it to a similar degree as other teachers. Future research should examine whether teachers rely on students' body size and ethnicity when making decisions in other situations that were not presented in our study. For example, teachers might make greater use of this information when making decisions that necessitate excluding, rather than including, children (e.g., selecting someone to sit out of an activity). Finally, our findings raise the possibility that other key players in the overweight or ethnic-minority child's social and academic environment are more central to their difficulties. Peers, for example, play an important role in children's social and academic environments at school. Although teachers may not use body size and ethnicity as a basis for student selection, one can readily imagine that some children use these criteria when choosing a teammate in gym class or a study partner for a science project.

Teachers' heavy reliance on attractiveness and affect across decision-making contexts stands in stark contrast to their limited use of body size and ethnicity. Previous researchers have minimized variation in body size when investigating the influence of student attractiveness on teachers' attitudes and behaviors, by using only head shots of students or depicting only average-weight students. In contrast, we allowed both characteristics to vary substantially in our photo stimulus set and minimized the relationship between body size and attractiveness to the extent possible when selecting stimuli. By tightly controlling the covariation between the body size and the attractiveness of the stimuli, we were able to distinguish between the patterns of results for attractiveness compared to body size. The divergence in the findings for attractiveness and body-size information in the present study indicates that aspects of attractiveness that are unrelated to body size may exert a significant influence on teacher decision making. Facial affect was a significant correlate of, though not synonymous with, attractiveness. Some teachers chose happy and attractive children in the decision-making tasks, while others preferred those who were smiling, regardless of attractiveness, or highly attractive but unhappy-looking girls.

The impact of body size and affect on attractiveness raises questions about what exactly attractiveness is and what aspects of attractiveness influence teacher decisions. Perhaps attractiveness consists of multiple components that vary in stability, such that some aspects routinely suggest attractiveness (e.g., body size), whereas other aspects (e.g., emotional expression) may be more malleable and contextually bound. Regardless, teachers' uniformly heavy reliance on attractiveness when selecting students for common classroom tasks is discouraging and suggests the importance of intervention efforts designed to minimize this influence. Future research examining the construct of attractiveness is important to further understand why it is such a reliably important variable to teacher expectations and behaviors, independent from facial affect and body size.

Some variability in teachers' utilization of ethnicity, body size, affect, and attractiveness emerged, but the overwhelming majority of teachers used affect and attractiveness far more than the other dimensions. Given the homogeneity of the parameter estimates, it was unsurprising that teachers' individual differences in utilization patterns were unrelated to the assessed individual-differences variables. In sum, PREFMAP analyses of teachers' choice data demonstrated that teachers relied primarily on students' affect and attractiveness when making decisions in common classroom contexts.

### *Teachers' Preferred Directions of Utilized Student Characteristics in Decision Making*

When examining teachers' preferred directions along heavily utilized dimensions, we anticipated that teachers not only would rely heavily on body size and ethnicity when making decisions but also would exhibit strong preferences for lighter, nonminority students. Few teachers displayed strong utilization of body size and ethnicity, however, and these teachers' preferred directions were distributed similarly across the two ends of the dimensions. In other words, teachers did not display systematic preferences for light students over heavy students or Caucasian or Asian American students over African American students. These findings are inconsistent with the marked social and academic difficulties reported by heavier and ethnic-minority students, and they suggest the importance of examining teacher decision making in other contexts (e.g., exclusionary situations) and investigating peers' decision making in school contexts. Further examining the cognitive processes involved in person perception may yield greater understanding of how stigmatized information is used when varying amounts of information are known about a person. For instance, does an individual's ethnicity become less important to person perception and to decisions based on these perceptions as additional person information becomes available? Such information about how teachers process ethnicity information relative to other important student information could raise questions about real-world interventions, such as the training offered by many school districts designed to enhance teachers' cultural sensitivity to and awareness of ethnically based biases.

Almost all of the teachers who showed strong utilization of affect and attractiveness routinely selected happy-looking, attractive children, although a few teachers systematically chose sad-looking or unattractive children. This overwhelming preference for attractive children is cause for concern and consideration of efforts to diminish this effect, as the stable aspects of attractiveness do not necessarily imply intelligence, responsibility, likability, or academic potential any more than body size or ethnicity do.

Our efforts to enhance the internal validity of our conclusions necessarily constrained the ecological validity of our findings. Thus, one should use caution when generalizing these findings to different student and teacher populations, experimental and stimulus conditions, and decision-making contexts. For instance, we included only girls in the stimulus set (i.e., we did not include gender as a dimension in the stimulus set) to constrain the dimensions being investigated to a tractable number, and the extent to which similar findings would emerge for teacher processing of boys is unknown. Similarly, although we did not find any processing differences across decision-making contexts, such differences

might emerge in other situations or if different students attributes were examined. We also purposely limited the amount of time that teachers had to examine the photo stimuli in an effort to create an experimental situation that was as analogous as possible to ones in which teachers must make rapid decisions, but we recognize that teachers often have longer to deliberate in many other significant classroom situations. Therefore, the present study was quite limited in its external validity, relative to the abundance of rich observational studies in this area, and future research should examine the convergence of the findings in the present study with observed teacher behavior in classroom situations.

### *Implications and Future Directions*

The present study relied on well-developed methods drawn from cognitive science to investigate the importance of several competing, well-researched, stigmatized characteristics to teachers' perceptions and decision making in common classroom-relevant situations. Using a study design that placed a premium on internal validity while incorporating significant externally valid features, we aimed to better understand teachers' processing of students in controlled decision-making contexts in an effort to supplement the existing research in educational psychology that has used other study designs, such as observational methods. Teachers attended to body size, ethnicity, affect, and attractiveness but unexpectedly relied primarily on affect and attractiveness when selecting students in four common classroom contexts. Teachers also exhibited a marked preference for happy, attractive girls across contexts in this study. One implication of these findings is that teachers may be inadvertently communicating that happy or attractive students are more capable or responsible than students who are have less positive affect or are less attractive. The current work suggests that it may be useful for teachers to attend more to how they are selecting students in these situations involving rapid classroom decision making.

This study is intended to be only a first step in a program of research aimed at understanding teachers' attention to and decision-making processes involving students, particularly those from traditionally stigmatized groups. Future work in this line of research can and should integrate other real-world variables of interest to educators. For instance, researchers should examine teacher decision making in a wider array of classroom situations, as well as other academically relevant situations and social situations. In addition, other theoretically important student information, such as the previous year's school performance, could be added in a standardized fashion to the stimulus set via short descriptive phrases at the bottom of each stimulus photo to increase ecological validity in a standardized fashion. Another future direction entails conducting the same study with older children depicted in photographs, because research indicates that the stigma associated with being overweight increases as children age and that older children are viewed as more responsible for their own condition. Moreover, teachers' striking tendency not to select unattractive children warrants further consideration, as this may exacerbate perceptions of unattractive children as less popular, intelligent, and friendly (Langlois et al., 2000). Finally, the relationship between teacher processing patterns and other teacher characteristics should continue to be investigated. For instance, teachers' own concerns about body shape and weight might

heighten their attention to variability in students' body size. Similarly, ethnic-minority teachers might process student ethnicity information differentially.

Better understanding how teachers think about and make decisions in the classroom, beginning with how they use student information to inform their decisions, may have implications for improving student learning and teacher training. For example, effective teachers may be systematically processing classroom information differently than less effective teachers. Although this study focused on how teachers attend to and utilize four student characteristics, similar work could be conducted examining other complex teacher behaviors that are important to student education, such as problem solving and communication, to understand where in their processing more versus less effective teachers differ. Having a better understanding of the way successful teachers process student information and recognizing the effective components in successful teachers' information processing could be instructive to other teachers by leading to increasingly specific, effective training for new teachers.

Experimental research also could help elucidate how individual differences among teachers impact teaching behaviors and student learning. In the present study, participants reported about some aspects of their teaching experience and various philosophies about teaching, such as whether all children have the potential to succeed and whether teachers should give more attention to struggling children. Although there were no systematic relationships of significance between these variables and which student characteristics teachers attended to or used in the classroom-relevant contexts in this study, there seems to be great potential for examining more teacher variables across different aspects of cognitive processing and teaching behaviors in future work. Experimental work could help determine, for instance, how teachers who believe that all children have the potential to succeed differ in their teaching style compared to those who do not. Such egalitarian teachers may be more likely to attend to negative facial affect, and they also may engage in a whole host of other thoughts or behaviors that are distinct from teachers who believe otherwise.

More generally, the present work highlights the feasibility and potential utility of translating performance-based paradigms drawn from cognitive science to investigate individual differences in complex social perception, even though these methods traditionally have been used to study normative processing of simple, highly artificial stimuli (Treat et al., 2001, 2002, 2007; Viken et al., 2002). It also serves to illustrate how highly controlled experimental work can be used to complement more externally valid research to better understand the processes underlying the behavioral phenomenon of interest. In particular, the similarity- and preference-ratings paradigms, in conjunction with scaling techniques, should be used more widely to investigate the role of attention and decision-making processes in more complex social phenomena, such as stigma and prejudice, which are particularly important to investigate in educational contexts. These paradigms allow for the simultaneous examination of multiple person attributes, which is more consistent with what perceivers must do in the real world. They also allow for greater experimental control and clearer interpretation of results than studies that maximize external validity, such as those using observational designs. Most important, investigating specific stages in information processing using such performance-based paradigms will provide a more

detailed understanding of how person features are processed and used in decision making, which may enhance the effectiveness of teacher training workshops.

Received November 3, 2005

Revision received June 28, 2007

Accepted July 3, 2007 ■

The main purpose of the *Journal of Educational Psychology* is to publish original, primary psychological research pertaining to education across all ages and educational levels. A secondary purpose of the *Journal* is the occasional publication of exceptionally important theoretical and review articles that are pertinent to educational psychology.

**Manuscript preparation.** Authors should prepare manuscripts according to the *Publication Manual of the American Psychological Association* (5th ed.). Manuscripts may be copyedited for bias-free language (see chap. 2 of the *Publication Manual*). Formatting instructions (all copy must be double-spaced) and instructions on the preparation of tables, figures, references, metrics, and abstracts appear in the *Manual*. For APA's Checklist for Manuscript Submission, see [www.apa.org/journals](http://www.apa.org/journals). **Abstract and keywords.** All manuscripts must include an abstract containing a maximum of 180 words typed on a separate page. After the abstract, please supply up to five keywords or brief phrases. **References.** References should be listed in alphabetical order. Each listed reference should be cited in text, and each text citation should be listed in the References. Basic formats are as follows:

- Haag, L., & Stern, E. (2003). In search of the benefits of learning Latin. *Journal of Educational Psychology*, 95, 174–178.
- Bollen, K. A. (1989). *Structural equations with latent variables*. New York: Wiley.
- Johnson, D. W., & Johnson, R. T. (1990). Cooperative learning and achievement. In S. Sharon (Ed.), *Cooperative learning: Theory and research* (pp. 173–202). New York: Praeger.

Adequate description of participants is critical to the science and practice of educational psychology; this allows readers to assess the results, determine generalizability of findings, and make comparisons in replications, extensions, literature reviews, or secondary data analyses. Authors should see guidelines for sample-subject description in the *Manual*. Appropriate indexes of effect size or strength of relationship should be incorporated in the results section of the manuscript (see pp. 5, 25–26 of the *Manual*). Information that allows the reader to assess not only the significance but also the magnitude of the observed effects or relationships clarifies the importance of the findings. **Figures.** Graphics files are welcome if supplied as Tiff, EPS, or PowerPoint. High-quality printouts or glossies are needed for *all* figures. The minimum line weight for line art is 0.5 point for optimal printing. When possible, please place symbol legends below the figure image instead of to the side. Original color figures can be printed in color at the editor's and publisher's discretion provided the author agrees to pay \$255 for one figure, \$425 for two figures, \$575 for three figures, \$675 for four figures, and \$55 for each additional figure.

**Publication policies.** APA policy prohibits an author from submitting the same manuscript for concurrent consideration by two or more publications. APA policy regarding posting articles on the Internet may be found at [www.apa.org/journals](http://www.apa.org/journals). In addition, it is a violation of APA Ethical Principles to publish "as original data, data that have been previously published" (Standard 8.13). As this is a primary journal that publishes original material only, APA policy prohibits publication of any manuscript or data that have already been published in whole or substantial part elsewhere. Authors have an obligation to consult journal editors concerning prior publication of any data on which their article depends. In addition, APA Ethical Principles specify that "after research

results are published, psychologists do not withhold the data on which their conclusions are based from other competent professionals who seek to verify the substantive claims through reanalysis and who intend to use such data only for that purpose, provided that the confidentiality of the participants can be protected and unless legal rights concerning proprietary data preclude their release" (Standard 8.14). Authors must have available their data throughout the editorial review process and for at least 5 years after the date of publication.

**Masked review policy.** Because the *Journal* has a masked review policy, authors submitting manuscripts are required to include, with each copy of the manuscript, a cover sheet that shows the title of the manuscript, the authors' names and institutional affiliations, the date the manuscript is submitted, and footnotes identifying the authors or their affiliations. The first page of the manuscript should omit the authors' names and affiliations but should include the title of the manuscript and the date it is submitted. Every effort should be made by the authors to see that the manuscript itself contains no clues to their identities. Authors are required to state in writing that they have complied with APA ethical standards in the treatment of their sample, or to describe the details of treatment. A copy of the APA Ethical Principles may be obtained at [www.apa.org/ethics/](http://www.apa.org/ethics/) or by writing the APA Ethics Office, 750 First Street, NE, Washington, DC 20002-4242. APA requires authors to reveal any possible conflict of interest in the conduct and reporting of research (e.g., financial interests in a test procedure, funding by pharmaceutical companies for drug research). Authors of accepted manuscripts will be required to transfer copyright to APA.

**Permissions.** Authors of accepted papers are required to obtain and provide to the editor on final acceptance all necessary permissions to reproduce in print and electronic form any copyrighted work, including, for example, test materials or portions thereof and photographs of people.

**Supplemental materials.** APA can now place supplementary materials online, which will be available via the published article in the PsycARTICLES database. To submit such materials, please see [www.apa.org/journals/authors/suppmaterial.html](http://www.apa.org/journals/authors/suppmaterial.html) for details. Authors of accepted papers will be asked to work with the editor and production staff to provide supplementary materials as appropriate.

**Submission.** Authors should submit their manuscripts electronically via the Manuscript Submission Portal at [www.apa.org/journals/edu](http://www.apa.org/journals/edu) (follow the link "Submit Manuscripts Electronically"). A checklist for manuscript submission, including guidelines for preparing the electronic file, can be found at [www.apa.org/journals/](http://www.apa.org/journals/). Correspondence regarding manuscripts should be sent to the Editor, Art Graessen, University of Memphis, Journal of Educational Psychology, 202 Psychology Building, Memphis, TN 38152-3230. In addition to addresses and phone numbers, authors should supply e-mail addresses, as most communications will be by e-mail. Fax numbers, if available, should also be provided for potential use by the editorial office and later by the production office. Authors should keep a copy of the manuscript to guard against loss. E-mail correspondence may be addressed to [jedgar@memphis.edu](mailto:jedgar@memphis.edu).

**Preparing files for production.** If your manuscript is accepted for publication, please follow the guidelines for file formats and naming provided at [www.apa.org/journals/authors/preparing\\_files.html](http://www.apa.org/journals/authors/preparing_files.html). If your manuscript was mask reviewed, please ensure that the final version for production includes a byline and full author note for typesetting.

# Intervening in Children's Lives

## An Ecological, Family-Centered Approach to Mental Health Care

Thomas J. Dishion and Elizabeth A. Stormshak

**M**ental health interventions for children and adolescents often flow from adult clinical models, which emphasize individual change. Yet, to accomplish long-lasting change for children and adolescents, services need to consider developmental norms, the developmental status of the child or adolescent, and the fact that mental health issues for this population are embedded in family, peer, and sibling relationships. In *Intervening in Children's Lives: An Ecological, Family-Centered Approach to Mental Health Care*, the authors describe a family-centered approach that engages children, adolescents, and their families, leveraging their motivation to change. Never before has there been a comprehensive, systematic framework for linking empirically supported interventions for this clinical population. Useful as both a preventive checkup and a more intensive intervention, this approach may be delivered in schools and other community settings to have the greatest public health impact.

The literature reveals promising findings, in that highest-risk youth are more likely to respond well to ecologically based interventions, and this approach is consistent with others showing long-lasting effects. 2007. 320 pages. Hardcover.

List: \$69.95 ■ APA Member/Affiliate: \$49.95 ■ ISBN 1-59147-428-0 ■ Item # 4317115 ■ ISBN-13: 978-1-59147-428-9

# BULLYING PREVENTION

*Creating a Positive School Climate  
and Developing Social Competence*

PAMELA ORPINAS AND ARTHUR M. HORNE

**B**ullying is the most prevalent form of violence in American schools. In their new book *Bullying Prevention*, authors Pamela Orpinas and Andy Horne bring together years of experience in research and applied behavioral sciences to show how educators, school psychologists, counselors, and other professionals can address the problem of bullying and aggression in schools.

Readers will find definitions, statistics, and theories that will help them identify and characterize bullying. They will learn about the authors' School Social Development and Bullying Prevention Model, a blueprint for schools that students, teachers, and parents enjoy being a part of. This model shows how school professionals can prevent and reduce bullying by creating a positive environment and by ensuring all children have the social skills to communicate well and solve problems without aggression. The book has guidance in selecting research-based bullying prevention programs, and steps for assessing a school's needs and for evaluating a program's effectiveness.

The book also offers practical strategies for helping the children who are targets of bullying, and discusses counseling and family interventions for children who continue to bully despite positive changes in the school and classroom environment. A rich resource section contains a wide range of bullying-related readings, manuals, and tools available on the Internet. 2006. 320 pages. Hardcover.

## CONTENTS:

Introduction

### ■ PART I.

Understanding

the Problem ■ Chapter 1. Bullies: The Problem and the Impact

■ Chapter 2. Risks and Protective Factors for Bullying and Aggression

■ Chapter 3. Theoretical Perspectives on Bullying and Aggression

### ■ PART II. Addressing the Problem: Universal Interventions

■ Chapter 4. School Social Competence Development and Bullying

Prevention Model: The School ■ Chapter 5. School Social Competence

Development and Bullying Prevention Model: The Student ■ Chapter 6.

Evaluation of Bullying and Aggression Problems and Intervention

Programs ■ Chapter 7. Selection and Implementation of Universal

Bullying Prevention Programs ■ PART III. Addressing the Problem:

Persistent Bullies ■ Chapter 8. Persistent Bullying: Counseling

Interventions ■ Chapter 9. Persistent Bullying: Family Interventions

■ Chapter 10. Helping Children Who Are the Targets of Bullying

# Child Development and Social Policy

## KNOWLEDGE FOR ACTION

Edited by J. Lawrence Aber, Sandra J. Bishop-Josef, Stephanie M. Jones, Kathryn Taaffe McLearn, and Deborah A. Phillips

Over the past 25 years, the intersection of developmental psychology and public policy has become an increasingly active and important domain for researchers, policymakers, children's rights advocates, and practitioners. At the forefront of the child development research and social policy movement is Edward Zigler, whose "knowledge for action" approach has revolutionized the way public policy is enacted to better serve vulnerable youth populations. *Child Development and Social Policy: Knowledge for Action* expands on Dr. Zigler's work in integrating the fields of child development and social policy, while using scientific knowledge for action as the model.

Contributors discuss these key questions: What are the most powerful research insights of the last 30 years that promote effective action for children and families? What are the most powerful constraints or limits of our knowledge base to promote effective action for children and families? What are the primary components of short-term research agenda to make the most powerful difference for children and families?

This edited volume focuses on both the influence of social policy on children's development and the unique perspective, insight, and skills that developmentalists bring to this policy and its formation. Programs to ensure good beginnings for all children are discussed, while the needs of those who are most vulnerable are also addressed. 2007. 352 pages. Hardcover.

# Effects of Small-Group Tutoring With and Without Validated Classroom Instruction on At-Risk Students' Math Problem Solving: Are Two Tiers of Prevention Better Than One?

Lynn S. Fuchs, Douglas Fuchs, Caitlin Craddock,  
Kurstin N. Hollenbeck, and Carol L. Hamlett  
Vanderbilt University

Christopher Schatschneider  
Florida State University

This study assessed the effects of small-group tutoring with and without validated classroom instruction on at-risk students' math problem solving. Stratifying within schools, 119 3rd-grade classes were randomly assigned to conventional or validated problem-solving instruction (Hot Math, schema-broadening instruction). Students identified as at risk ( $n = 243$ ) were randomly assigned, within classroom conditions, to receive or not receive Hot Math tutoring. Students were tested on problem-solving and math applications measures before and after 16 weeks of intervention. Analyses of variance, which accounted for the nested structure of the data, revealed that the tutored students who received validated classroom instruction achieved better than the tutored students who received conventional classroom instruction (effect size = 1.34). However, the advantage for tutoring over no tutoring was similar whether students received validated or conventional classroom instruction (effect sizes = 1.18 and 1.13). Tutoring, not validated classroom instruction, reduced the prevalence of math difficulty. Implications for responsiveness-to-intervention prevention models and for enhancing math problem-solving instruction are discussed.

**Keywords:** mathematics, mathematics instruction, mathematics disability

**Supplemental materials:** <http://dx.doi.org/10.1037/0022-0063.100.3.491.supp>

Mathematics word problems require the transfer of knowledge to novel situations, and this form of transfer can be difficult to effect (cf. Bransford & Schwartz, 1999; Mayer, Quilici, & Moreno, 1999), especially for primary-grade children (Durnin, Perrone, & MacKay, 1997; Foxman, Ruddock, McCallum, & Schagen, 1991, cited in Boaler, 1993; Larkin, 1989). Whereas a calculations problem is already set up for solution, a word problem requires students to use text to determine what information is unknown and to construct and solve a number sentence for finding that unknown information. So, although calculation skill is foundational to word problems (e.g., L. S. Fuchs et al., 2006), it seems likely that for some students, word-problem skill will not develop automatically from instruction on math calculations, but rather that instruction needs to be designed specifically to prevent difficulty with word problems.

The context for preventing academic difficulty in the schools has changed over the past 5 years with the introduction of multi-tiered prevention systems.<sup>1</sup> Adapted from the health care system, school-based multi-tier prevention systems typically involve three tiers. The first tier is research-principled or validated classroom instruction. Students who are deemed at risk for difficulty with the classroom program (AR students), usually on the basis of screening near the beginning of the school year, also receive a second tier of prevention, with a standard, validated small-group tutoring protocol (that can be expected to benefit most students). Only students who prove unresponsive to classroom instruction and to tutoring are referred for a comprehensive evaluation to consider the possibility of a disability that requires a third, more individualized tier of prevention, usually special education. Because such a multitier prevention system involves assessing a student's responsiveness-to-intervention (RTI), it is conventionally referred to as an *RTI prevention system* (e.g., see Vaughn & Fuchs, 2003).

Most RTI studies have addressed reading (e.g., D. Fuchs, Compton, Fuchs, & Davis, in press; Vaughn, Linan-Thompson, & Hickman, 2003; Vellutino et al., 1996). In mathematics, where fewer studies have been conducted, the bulk of the literature has been conducted by VanDerHeyden, Witt, and their colleagues. For example, VanDerHeyden, Witt, and Gilbertson (2007) screened

---

<sup>1</sup> In the RTI literature, any instructional program that is grade-level appropriate is conceptualized as a form of prevention, not remediation. In the present study, instruction focused on third-grade curricular targets, making the use of the term *prevention* appropriate.

elementary-grade students on grade-level computational fluency. Classrooms scoring below a given criterion received classroom instruction to build computational fluency. Individual students who scored below the 16th percentile of their own class, with classroom intervention when needed, were assessed to determine whether students could score above the 16th percentile if offered a reward. Only students who could not achieve the criterion even when rewarded entered tutoring, which involved 10 min per day of computation instruction with modeling, guided practice with immediate error correction, independent timed practice with slightly delayed error correction, and the opportunity to earn a reward. VanDerHeyden et al. evaluated this multi-tiered RTI math prevention model, using a multiple-baseline across-schools design with five schools. Referrals to and evaluations for special education decreased with implementation, but effects on students' math performance were not reported. In related work, VanDerHeyden and Witt (2005) used a similar model to screen first and second graders in one school, using basic fact assessments. With the subset of children who scored poorly, nine practice sessions with feedback and reinforcement were conducted to increase basic fact fluency. On the basis of these sessions, the researchers identified nonresponders and examined decision utility with respect to final outcomes, but they did not explore effects on student learning.

These studies and others in VanDerHeyden's line of work are ambitious and important, but they are restricted to calculations, rely on a narrow approach to math instruction, and do not assess effects on students' math performance. L. S. Fuchs et al. (2005) extended this line of work by conducting a randomized field trial to assess the effects of second-tier small-group tutoring on a broader first-grade math curriculum, including number sense and concepts, addition and subtraction concepts and procedures, number combinations, missing addends, place value, and word problems. A more comprehensive instructional design and a more sustained intervention were used, and the study supported the efficacy of the small-group tutoring on students' learning outcomes. However, the focus on word problems was limited to 1 week of the 16-week tutoring program, and the researchers did not consider whether tutoring efficacy was enhanced when classroom instruction relied on a validated approach.

In fact, we identified only one prior RTI or prevention study that assessed the efficacy of tutoring with and without validated classroom instruction. It was conducted with first graders and assessed reading tutoring. Gilbert, Compton, Fuchs, Fuchs, and Schatschneider (2007) showed that tutoring was similarly effective for AR students with or without validated classroom reading instruction as the backdrop for tutoring. However, in contrast to most RTI models where risk status is identified on the basis of initial screening, AR students entered Gilbert et al.'s study only after a full semester of progress monitoring showed inadequate response to the classroom instructional program; thus, it is not surprising that the nature of classroom instruction during tutoring did not enhance tutoring's efficacy.

The issue of how tutoring interacts with classroom instruction among AR students who may have poor learning outcomes is important for designing efficient and effective RTI prevention systems. If tutoring is differentially efficacious when combined with validated classroom instruction, then both tiers are critical, and classroom instruction needs to be designed deliberately with AR students in mind, even when they receive tutoring. By contrast,

if tutoring promotes comparable outcomes regardless of the classroom instructional context, then findings would set the stage for research on whether tutoring might occur as a replacement for, rather than as a supplement to, classroom instruction. Tutoring as a replacement for classroom instruction would make RTI prevention systems more feasible and efficient and would permit resources to be infused at the tutoring tier. Of course, in considering tutoring efficacy as a function of the classroom's instructional context, it is important not only to compare the response of AR students who do and do not receive tutoring, but also to contrast the learning of those AR students against not-at-risk (NAR) students. This has not been addressed in prior work.

The purpose of the present study, therefore, was to examine students' mathematics problem-solving learning and to explore the prevalence of mathematics difficulty as a function of validated classroom prevention, as a function of small-group tutoring, and as a function of whether tutoring occurs with or without validated classroom instruction. (We refer to *small-group tutoring* as *tutoring* in this article.) We describe the theoretical basis for our approach to word-problem instruction and summarize previous related work. Then we consider previous studies assessing the effects of one or two tiers of prevention on the prevalence of mathematics difficulty. Finally, we review the study's purpose and design.

### Transfer, Schema Theory, and Related Work on Word-Problem Instruction

The mathematics education literature shows that children experience difficulty transferring the math competence they develop in school. For example, Larkin (1989) demonstrated that children fail to apply simple computational skills when problems change in minor ways. Other work (Foxman, Ruddock, McCallum, & Schagen, 1991, cited in Boaler, 1993) has illustrated how students fail to realize connections between math problems presented in and out of context. Such findings are supported by theoretical frameworks for understanding the development of transfer that challenge the assumption of vertical transfer, whereby mastery of simple skills facilitates acquisition of more complex skills (Gagne, 1968; Resnick & Resnick, 1992). The notion of vertical transfer has been replaced with the concept of lateral transfer, by which children recognize problems across numerous experiences to abstract generalized problem-solving strategies.

Some refer to the abstraction of generalized problem-solving strategies as the *development of schemas* (A. L. Brown, Campione, Webber, & McGilly, 1992; Gick & Holyoak, 1983). A schema is a category that encompasses similar problems; it is a problem type (Chi, Feltovich, & Glaser, 1981; Gick & Holyoake, 1983; Mayer, 1992; Quilici & Mayer, 1996). The broader the category for the problem type, the greater the probability that individuals will recognize connections between familiar and novel problems so that they will know when to apply the solution methods they have learned. Essentially, students expand the domain of problems for which they recognize that they have the mathematical means to find answers, thereby facilitating transfer to novel problems. To facilitate schema development, teachers must first teach problem-solution rules, as they conventionally do. Then, however, teachers must help students develop schemas and awareness of those schemas (Cooper & Sweller, 1987) and must provide students with a wealth of problem-solving activities that emphasize knowledge

application (J. S. Brown, Collins, & Duguid, 1989; Prawat, 1992). The hope is that schemas can influence behavior in a broad set of situations and thereby affect breadth of learning or transfer (A. L. Brown et al., 1992; Glaser, 1983). Research has substantiated the importance of mastering rules for problem solution (e.g., Mawer & Sweller, 1985; Sweller & Cooper, 1985), but less is known about how to help students develop schemas and awareness of those schemas (e.g., Bransford & Schwartz, 1999; Cooper & Sweller, 1987; Mayer et al., 1999).

Some studies have relied on explicit instruction based on schema theory to enhance word-problem skill. Working primarily at the second or third tier of the RTI prevention system in small groups, Jitendra and colleagues have demonstrated acquisition, maintenance, and transfer effects for students with serious math deficits or with risk for math difficulty at eighth grade (Jitendra, DiPipi, & Perron-Jones, 2002), sixth grade (Xin, Jitendra, & Deatline-Buchman, 2005), and third and fourth grades (Jitendra et al., 1998, 2007; Jitendra & Hoff, 1996). In our work, we have also relied on schema theory. In contrast to the studies of Jitendra and colleagues, our work has been conducted exclusively at third grade, with more difficult problem types, with a focus on far transfer that extends beyond the transfer requirements in Jitendra's studies, and with a key difference in the way schema theory is applied. In instruction similar to Jitendra's schema-based strategy instruction, we have taught students to understand the underlying mathematical structure of the problem type, to recognize the basic problem-type category, and to solve the problem type. In contrast to Jitendra's teaching methods, we have incorporated a fourth instructional feature by explicitly teaching students to transfer their problem-solving skills. In keeping with Cooper and Sweller (1987), our goal has been to help students recognize connections between problems like those worked during instruction and problems with unexpected features, such as problems that include irrelevant information, that present a novel question requiring an extra step, that include relevant information presented in charts or graphs, or that combine problem types, and so on. Our hope has been that the addition of explicit transfer instruction would lead to more flexible and successful problem solving. We refer to the combination of all four instructional components as *schema-broadening instruction* (SBI). Teachers and students refer to this approach as *Hot Math*.

In our first randomized field trial, L. S. Fuchs, Fuchs, et al. (2003b) separated the effects of the first three instructional components (teaching students to understand the underlying mathematical structure of the problem type, to recognize the basic schema for a problem type, and to solve the problem type) from those of the last instructional phase (explicitly teaching students to transfer). The study was conducted at the first tier of the RTI prevention system, in general education classrooms, with whole-class instruction, and with all students for whom we had consent. The basic word-problem types targeted for instruction were more complex than had yet been studied with the third graders, including finding half, step-up functions, two-step problems involving pictographs, and two- and three-step shopping list problems. Also, far transfer was assessed on taught and untaught problem types within a highly novel and complex context that resembled real-life problem-solving situations. Third-grade classes were randomly assigned to teacher-designed word-problem instruction, to experimenter-designed instruction on the first three instructional

components, or to experimenter-designed SBI that incorporated the first three components but also explicitly taught students to transfer. With the addition of this last instructional component, teachers explained how problem features, such as format or vocabulary, can make problems seem unfamiliar without modifying the problem type or the required solution rules; they discussed examples, emphasizing that they had the same problem types as superficial features, such as format or vocabulary, changed; they provided practice in sorting novel problems in terms of changes in superficial problem features and in terms of solving those problems; and they prompted students to search novel problems for familiar problem types. Results indicated that on near- and far-transfer word-problem tasks, Hot Math SBI (i.e., all four components) strengthened problem-solving performance over and beyond experimenter-designed instruction that addressed only the first three components (understanding the underlying mathematical structure, recognizing the basic schema, and solving problems) and beyond teacher-designed instruction.

In subsequent work (L. S. Fuchs, Fuchs, Finelli, et al., 2004), SBI that addressed transfer instruction on three superficial features was more effective than SBI that addressed transfer instruction on six superficial features. However, the present study is the first to assess the efficacy of SBI tutoring on relatively complex problem types. Moreover, in our own prior work, as in other math and reading RTI research, the combined and separate effects of classroom instruction and tutoring have not been assessed, and the prevalence of math difficulty with one and/or two tiers of prevention has not been examined.

### Prevalence of Math Difficulty

Studies (e.g., Gross-Tsur, Manor, & Shalev, 1996; Lewis, Hitch, & Walker, 1994; Shalev, 2007) have indicated that 5%–9% of the school-age population experience some form of math disability. Four problems, however, limit the utility of available figures. First, much of the literature is limited to math facts and simple computation. Second, many studies do not rely on individual tests, as used in the schools to identify disability. Third, to recruit adequately large samples, high cut scores have often been applied. For example, Jordan and Hanich (2000) and Jordan and Montani (1997) demarcated math difficulty as falling below the 30th percentile on a group-administered test; Hanich, Jordan, Kaplan, and Dick (2001) used the 35th percentile. Russell and Ginsburg (1984) included students performing one level below their expected grade, and Geary (1990) identified children participating in Chapter 1 (in which mean study scores corresponded to percentile ranks of 25 in Grade 1 and 40 in Grade 2). Fourth, in the absence of sound prevention activities, math disability estimates may be artificially high because they fail to eliminate inadequate instruction as a possible explanation for low math achievement.

In the present study, we sought to address these problems. We focused on applied math problems. We investigated the prevalence of math difficulty on an individually administered math test as is done in the schools to identify disability, and we applied a cut score more similar to those used in the schools (i.e., 15th percentile). Finally, to understand how sound prevention activities may affect the prevalence of math disability, we examined disability prevalence with and without SBI classroom instruction and with and without SBI tutoring.

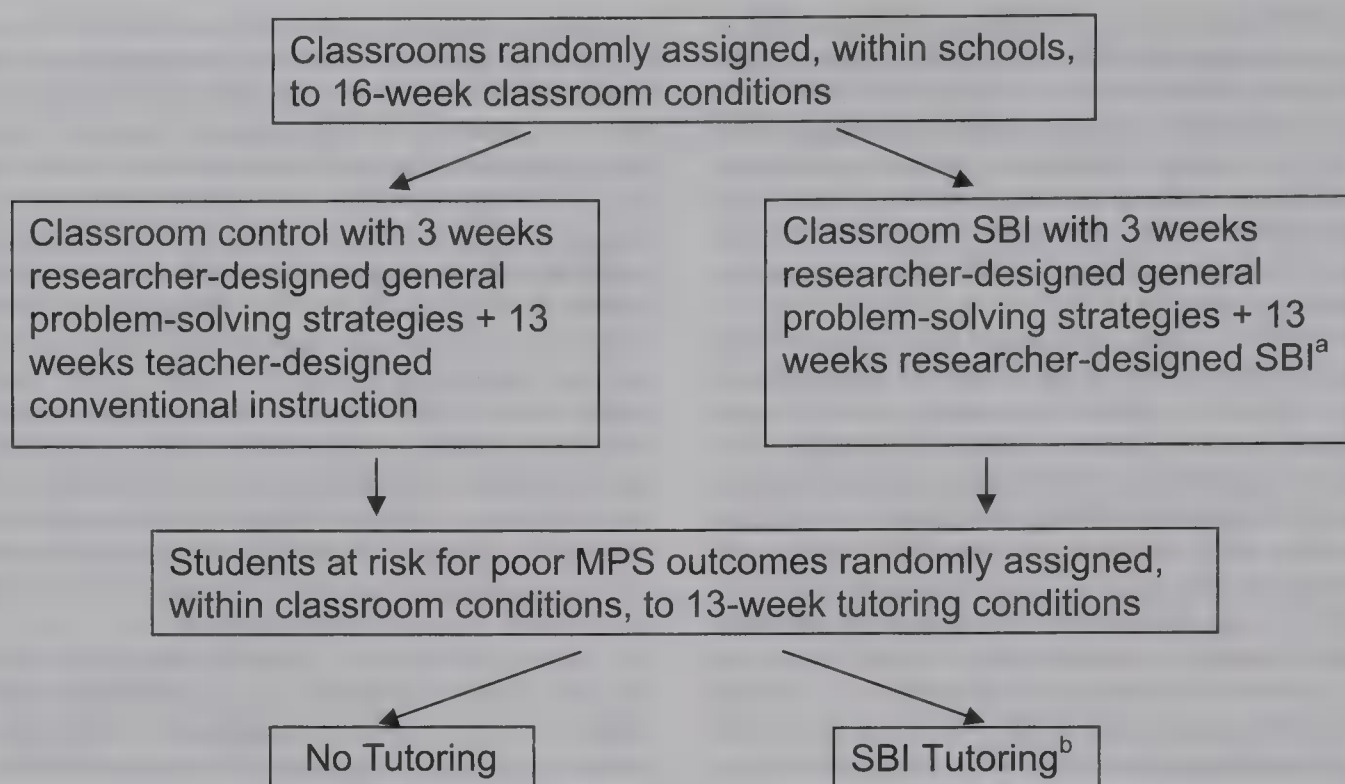

Figure 1. The study design is shown. SBI = schema-broadening instruction; MPS = math problem solving.

<sup>a</sup>In Years 1–3, SBI classrooms were randomly assigned to receive standard SBI or a variant of SBI. <sup>b</sup>In Years 1–2, SBI tutoring students were randomly assigned to receive standard SBI tutoring or a variant of SBI tutoring

### Study Purposes and Overview

The primary purpose of the present study was to assess the effects of SBI tutoring, with and without SBI classroom instruction, on AR students' math problem solving and on their learning relative to NAR peers. We also examined the prevalence of mathematics difficulty with and without one or two tiers of SBI math problem-solving prevention, and we assessed the efficacy of the classroom and tutoring SBI instructional protocols. Within schools, we randomly assigned third-grade classrooms to receive classroom SBI or to receive the math problem-solving instruction designed by their teachers. In these classrooms, we designated NAR and AR students on the basis of their incoming math scores and, within classroom conditions, randomly assigned AR students to continue in their classroom conditions with or without SBI tutoring. Students were pre- and posttested in a 3-week window before and after prevention occurred (see Figure 1 for the study design).

### Method

#### Participants

**Classrooms and their teachers.** In a southeastern metropolitan school district, 120 third-grade classrooms participated in this study. Stratifying so that each condition was represented approximately comparably in each school, we randomly assigned 40 classrooms to the control condition (i.e., 3 weeks of researcher-designed general math problem-solving instruction plus 13 weeks of teacher-designed math problem-solving instruction) and assigned 80 classrooms to the Hot Math SBI condition (i.e., 3 weeks of researcher-designed general math problem solving plus 13

weeks of researcher-designed SBI). The study occurred over 4 school years during a time when the school district was relatively stable.<sup>2</sup> One quarter of the sample entered the study each year. During the first 3 years, SBI classrooms were randomly assigned to Hot Math SBI or to a variant designed to strengthen Hot Math SBI (see Table 1 for a summary of the classroom SBI variants). In the first three cohorts, the effects of the two SBI conditions were not statistically significantly different, but both were reliably better than control. Therefore, we did not test a variant in Cohort 4 (all Cohort 4 teachers were randomly assigned to control or to the standard version of SBI). We considered all students in the SBI classrooms to have participated in one SBI condition; however, to assess SBI variants, we included cohort effects in the analytic model. One Cohort 3 classroom in the SBI condition left the study during the first month of participation because of the classroom teacher's personal reasons. The remaining 119 classroom teachers

<sup>2</sup> Across the 4 years of the study, the school district changed as follows. The student population increased from 69,445 to 70,140. The number of schools increased from 126 to 133. The number of teachers decreased from 4,831 to 4,809. The number of White students decreased from 31,460 to 28,483, whereas the number of Hispanics rose from 7,017 to 10,467, and the number of African Americans increased from 35,349 to 36,864. Students classified as having limited English proficiency increased by 1.9%; those classified with disabilities decreased by 1.6%. Per pupil spending increased from \$8,885 to \$9,300. In 2005–2006, a new math core instructional program was introduced (see description of classroom control condition). In terms of administration, the only significant change was the departure of the chief instructional officer. Because this occurred during the last month of implementation of the 4-year study, it did not affect instructional context.

Table 1  
Instructional Variants by Tier and by Cohort

Cohort	Variant	Incorporated as standard SBI in subsequent years
Classroom tier		
1	Once per week, RA teacher led discussion of how transfer features apply to a video portraying a real-life math situation that included second-grade problem types	No
2	In each session, in paired practice, students extended one partially developed problem into a specific problem type. This was guided by problem production steps. (What kind of problem? What do you know? What should you add?)	No
3	For every problem, students asked themselves meta-questions to guide the problem-solving process. (Who is the most important person in the story? What is the most important thing the who is doing? What question do we need to answer with math? What's the problem type? What transfer features are included?)	No
Tutoring tier <sup>a</sup>		
1	Self-regulated learning strategies incorporated within tutoring sessions	Yes and strengthened in Cohorts 2, 3, and 4 to enhance motivation
2	Drill-and-practice warm-ups to build fluency with a foundational skill necessary for the specific problem type	No

*Note.* When variants required additional time, students in the standard SBI condition had more practice to keep instructional time comparable. SBI = schema-broadening instruction; RA = research assistant.

<sup>a</sup>See text for more information.

were predominantly female (97.4% in control, 97.5% in SBI) and European American (79.5% in control, 66.7% in SBI; the teachers who were not European American were African American). In the control group, teachers had taught for an average of 14.18 years ( $SD = 10.49$ ), and in the SBI group, teachers had taught for an average of 16.09 years ( $SD = 10.27$ ). Average class size for the control group was 18.69 ( $SD = 2.40$ ), and average class size for the SBI group was 18.45 ( $SD = 2.62$ ). There were no significant differences on these variables by classroom condition.

Research assistants, not classroom teachers, delivered researcher-designed general problem-solving strategies instruction to all 119 classrooms during the first 3 weeks of instruction. For the final 13 weeks of instruction, research assistants delivered classroom SBI, whereas classroom teachers delivered conventional instruction. We refer to research assistants who taught general problem-solving strategies or classroom SBI as *RA teachers*, and we refer to the real classroom teachers as *classroom teachers*. Whenever an RA teacher was delivering instruction, the classroom teacher was present to help distribute materials, maintain order, and provide corrective feedback. (When there was more than one variant of classroom SBI, each RA teacher taught in both conditions.) We also note that the math program in all classrooms went beyond the instructional procedures described in the study; that is, experimental procedures were incorporated within the classroom teachers' broader mathematics instructional program. We describe research assistants later.

*Students.* To obtain a representative sample, we screened 2,023 students for whom we had consent. That is, in the 119 third-grade classrooms, we randomly sampled 1,200 students for participation, blocking within classrooms and within three strata: (a) 25% of students with scores 1 standard deviation below the mean of the entire distribution on the Test of Computational

Fluency (L. S. Fuchs, Hamlett, & Fuchs, 1990); (b) 50% of students with scores within 1  $SD$  of the mean of the entire distribution on the Test of Computational Fluency; and (c) 25% of students with scores 1 standard deviation above the mean of the entire distribution on the Test of Computational Fluency. Of these 1,200 students, 59 moved prior to posttesting (including 45 AR students; see later discussion). The 59 children who moved prior to posttesting were demographically comparable to the pupils who remained in the study. Among the remaining 1,141 students, IQ, as measured on the two-subset Wechsler Abbreviated Intelligence Scale (Wechsler, 1999), averaged 97.29 ( $SD = 13.93$ ). Standard scores on the Woodcock-Johnson III Tests of Achievement (WJ III; Woodcock, McGrew, & Mather, 2001) Applied Problems averaged 102.56 ( $SD = 13.60$ ), and standard scores on the Woodcock Reading Mastery Test-Revised (Woodcock, 1998) Word Identification averaged 100.83 ( $SD = 10.09$ ). Of these students, 559 (49.0%) were male, and 626 (54.9%) received subsidized lunch. Ethnicity was distributed as follows: 480 (42.1%) African American, 464 (40.7%) European American, 120 (10.5%) Hispanic, 17 (1.5%) Kurdish, and 60 (5.3%) other. Thirty-seven students (3.2%) were English language learners.

Among these students, we identified 288 students as AR for poor problem-solving outcomes. To derive a parsimonious equation for predicting problem-solving outcomes, we conducted regression analyses on a previous database (L. S. Fuchs, Fuchs, Prentice, et al., 2004) of third-grade students who had received Hot Math SBI. The final prediction equation included pretest performance on the immediate transfer problem-solving measure (see *Measures* section) and pretest performance on the Test of Computational Fluency (L. S. Fuchs et al., 1990). For each cohort, we rank ordered students on the predicted score and selected the lowest 72 students in that year's sample. Within cohort, we as-

signed these students to tutoring conditions, while stratifying by classroom condition. In this way, some AR students received neither classroom nor tutoring Hot Math SBI; some received classroom but not tutoring Hot Math SBI; some received tutoring but not classroom Hot Math SBI; and some received classroom and tutoring Hot Math SBI. Of the 288 AR students, 45 moved prior to posttesting. On demographic and pretest performance variables, the 45 children who moved prior to posttesting were comparable to the 243 pupils who remained in the study, and there were no significant interactions between AR students' tutoring condition and attrition status.

During the first 2 years of the study, AR students were randomly assigned to control (no tutoring) or to one of two versions of tutoring SBI. For Cohort 1, the two versions of SBI tutoring were SBI with and without self-regulated learning strategies; the addition of self-regulated learning strategies appeared promising (the cohort sample was too small to allow us to apply inferential statistics). For Cohort 2, we strengthened the motivation system within self-regulated learning strategies. Students were randomly assigned to receive SBI with strengthened self-regulated learning strategies, with and without drill/practice activities designed to build fluency with low-level skills. Strengthened self-regulated learning strategies appeared promising, but the drill/practice activities did not (again, the cohort sample was too small to allow us to apply inferential statistics). For Cohorts 3 and 4, we built power by randomly assigning AR students to only two tutoring conditions: control versus Hot Math SBI that incorporated strengthened self-regulated learning strategies. In our model, Hot Math SBI tutoring is treated as one condition; however, to gain insight into the effects of the variants, we considered cohort effects. (See Table 1 for a summary of the SBI variants.) Research assistants delivered SBI tutoring, and we refer to these research assistants as *RA tutors*. (When there was more than one variant of SBI tutoring, each RA tutor taught in both conditions.) Information on research assistants is provided later.

For the classroom factor, we had two conditions: classroom control and classroom SBI. For the tutoring factor, we had three conditions: NAR (i.e., not eligible for tutoring), AR control, and AR tutored. See Table 2 for demographics by classroom and tutoring conditions (for a table that provides this information by cohort as well, contact Lynn S. Fuchs). See Table 2 for standard scores on the Wechsler Abbreviated Intelligence Scale IQ, WJ III Applied Problems, and Woodcock Reading Mastery Test-Revised Word Identification, for raw scores on the Test of Computational Fluency (digits correct and problems correct), and for demographic data by classroom and by tutoring conditions (for tables with this information by cohort as well, contact Lynn S. Fuchs). We ran three-way analyses of variance on these performance data, using classroom condition, tutoring condition, and cohort as variables. The only significant effect was for tutoring condition. As expected, on each measure, NAR students scored significantly higher than both AR groups, which scored comparably to each other. We ran chi-square analyses to examine the relation between demographics and classroom condition; none was significant. For tutoring condition, we used one degree of freedom to examine the relation between demographics and risk status. Compared with AR students, NAR students were significantly less likely to receive subsidized lunch, to be African American, and to receive special education (but were comparably likely to be English language

learners). We used the other degree of freedom to examine the relations between demographics and the AR control group versus the AR tutored group; none was significant.

### Classroom Conditions

For a manual with the researcher-designed general problem-solving strategies, classroom SBI, or SBI tutoring teaching scripts and materials, contact Lynn S. Fuchs. Scripts and materials provided a road map for research assistants to implement the instructional methods. The scripts were studied, not read.

*Problem types.* We centered the study on four word-problem types that we chose from the district curriculum to ensure that classroom control students had instruction relevant to the study. The four problem types were *shopping list problems* (e.g., Joe needs supplies for the science project. He needs 2 batteries, 3 wires, and 1 board. Batteries cost \$4 each, wires cost \$2 each, and boards cost \$6 each. How much money does he need to buy supplies?), *half problems* (e.g., Marcy will buy 14 baseball cards. She'll give her brother half the cards. How many cards will Marcy have?), *step-up function or buying bags problems* (e.g., Jose needs 32 party hats for his party. Party Hats come in bags of 4. How many bags of party hats does Jose need?), and *two-step pictograph problems* (e.g., Mary keeps track of the number of chores she does on this chart [a pictograph is shown with a label; each picture stands for 3 chores]. She also took her grandmother to the market 3 times last week. How many chores has Mary done?).

*Classroom control condition.* To guide instruction relevant to the four problem types, classroom control teachers relied primarily on the core math instructional program. For Cohorts 1 and 2, this was Math Advantage (Burton & Maletsky, 1999). For Cohorts 3 and 4, this was Houghton Mifflin Math (Greenes et al., 2005). In both programs, instruction addressed one problem type at a time (as did SBI) and focused on the concepts underlying the problem type. In addition, a prescribed set of problem-solution rules was taught, with explicit steps for arriving at solutions to the problems presented in the narrative. There was no attempt to broaden students' schemas for these problem types to address transfer. However, in comparison to classroom SBI, classroom control group instruction provided more practice in applying problem-solution rules and provided greater emphasis on computational requirements. Classroom control group instruction was explicit and relied on worked examples, guided group practice, independent work with checking, and homework. Compared to Math Advantage, Houghton Mifflin Math had a greater emphasis on problem-solving strategies, including guiding questions to help students understand, plan, solve, and reflect on the content of problems (we note, however, that our analyses did not reveal cohort effects involving the control group).

In addition, the classroom control group (as well as the classroom SBI group) incorporated a 3-week unit on general problem-solving strategies designed and delivered by the researchers (see later discussion) to control for foundational problem-solving strategies that were necessary for but conceptually unrelated to SBI. Previous research (L. S. Fuchs, Fuchs, et al., 2003a) showed that this 3-week unit alone is insufficient to enhance outcomes on the math problem-solving measures used in the present study. We conceptualized the classroom control group as representing conventional classroom problem-solving instruction in order to esti-

Note. Standard scores are given for the WASI-IQ, the WJ-AP, and the WRMT-WID. Raw scores are given for the Comp Flu. SBI = schema-broadening instruction; NAR = not at risk; AR = at risk; WASI-IQ = Wechsler Abbreviated Scale of Intelligence; WJ-AP = Woodcock-Johnson III Tests of Achievement—Applied Problems; WRMT-WID = Woodcock Reading Mastery Tests—Word Identification; Comp. Flu = Test of Computational Fluency; Dig = digits correct; Prob = problems correct; AA = African American; EA = Euro-American; Hisp = Hispanic; ELL = English language learner.

mate the contribution of classroom SBI over conventional instruction.

*General problem-solving strategies instruction (classroom control and classroom SBI groups).* Classroom control and classroom SBI students received a researcher-designed 3-week (two lessons per week) instructional unit on general math problem-solving strategies, which was conceptually unrelated to SBI and was delivered by research assistants. It addressed making sure answers make sense, lining up numbers from text to perform math operations, checking computation, and labeling work with words, monetary signs, and mathematical symbols. These six lessons, each lasting 30–40 min, relied on worked examples with explicit instruction, dyadic practice, independent work with checking, and homework, for a total of 210 min.

*Classroom SBI.* After the classroom-SBI students received the 3-week general math problem-solving unit, they received four researcher-designed 3-week SBI units. Each SBI unit comprised six sessions. Also, two cumulative review sessions were delivered the week after winter break. In each unit, Sessions 1 and 5 lasted about 40 min; the others lasted about 30 min. This totaled 200 min per unit and 856 min across the units (including the two cumulative review sessions). Each 3-week unit addressed one of the four problem types: shopping list, buying bag, half, and pictograph.

Within each unit, the sequence of lessons was as follows. In Sessions 1–4, problem–solution instruction was delivered, with problems that varied only in their cover stories. A poster listing the steps of the solution method was displayed in the classroom. In Session 1, RA teachers addressed the underlying concepts and structural features for the problem type, presented a worked example, and as they referred to the poster, explained how each step of the solution method had been applied in the example. Students responded frequently to questions. After reviewing the concepts and presenting several worked examples in this way, RA teachers shared partially worked examples while students applied the solution steps. Students then completed one to four problems in dyads, where stronger students helped weaker students solve problems and check work with answer keys. Sessions 2–4 were structured similarly, with a greater proportion of time spent on partially worked examples and dyadic practice. Also, at the end of Sessions 2–4, students completed one problem independently. The teacher checked work against an answer key, and students graphed scores.

Sessions 5–6 were designed to broaden schemas, with each problem varying the cover story and one of the four superficial features addressed in SBI. RA teachers first taught the meaning of the word *transfer* and then taught the four superficial features (referred to as *transfer features*), which change a problem without altering its type or solution: A familiar problem type, for which a solution is known, can use unfamiliar vocabulary, can pose an additional question, can incorporate irrelevant information, and/or can combine problem types. A poster, *Transfer: Ways Problems Change*, was displayed. In Session 5, RA teachers explained the poster, illustrating each superficial feature with a worked example. They gradually moved to partially worked examples. Then, students worked in pairs to apply the solution method to problems that varied in their superficial features. In Session 6, RA teachers reviewed the four superficial features, using similar procedures, except that students spent more time working in dyads and then completed a problem independently, scored work against a key, and graphed scores.

*Delivery.* When more than one SBI variant was used for Cohorts 1–3, classroom research assistants had responsibility for classes in both SBI conditions. To ensure comparable mathematics instructional time across conditions, experimental sessions occurred within the confines of the classroom teachers' mathematics instructional block. At the end of the study, classroom teachers reported the number of minutes per week they spent on math, including time on this research project. Mean numbers of math instructional minutes (including researcher-designed general math problem-solving strategy instruction and SBI) were 274.23 ( $SD = 72.96$ ) and 282.50 ( $SD = 80.59$ ) for the classroom control group and for the classroom SBI group, respectively.

*Treatment fidelity.* Prior to the first delivery of each session, RA teachers agreed on the essential information in the script and made a checklist of points. Each session was audiotaped. At the study's end, two research assistants independently listened to tapes while completing the checklist to identify the percentage of points addressed. We sampled tapes so that, within conditions, RA teachers and lesson types were sampled equitably. In class-level control, one or two tapes were sampled per class (for Unit 1); in class-level SBI, six or seven tapes were sampled per class (distributed equally across Units 1–5). Inter-coder agreement, calculated on 20% of the sampled tapes, was 95.3%. The mean percentage of points addressed was 97.20 ( $SD = 3.06$ ) for classroom control and 96.71 ( $SD = 2.37$ ) for classroom SBI,  $F(1, 117) = 0.88$ ,  $p = .351$ .

### *Tutoring Conditions*

NAR and AR control students continued in their classroom conditions without modification, with one third of AR students randomly assigned to the tutoring control condition and two thirds of AR students randomly assigned to tutoring. AR tutored students received SBI tutoring. Tutoring SBI centered on the same four word-problem types.

Tutoring began after the general math problem-solving unit had been implemented, with AR students identified, randomly assigned, and scheduled for tutoring during the general math problem-solving unit. Tutoring addressed the four 3-week SBI units, with three tutoring sessions conducted each week and with two cumulative review sessions delivered the week after winter break. Tutoring groups included 2–4 students, and each session lasted 20–30 min (i.e., 225 min per unit and 940 min across the units, including the two review sessions). Each 3-week unit addressed one of the four problem types: shopping list, buying bag, half, and pictograph.

The content of Hot Math SBI tutoring mirrored the content covered in classroom SBI. However, in tutoring, the most difficult concepts from classroom SBI were targeted, manipulatives were incorporated more frequently, additional scaffolding to support student learning was used, and self-regulated learning strategies with tangible reinforcement (depending on cohort) were incorporated.

During the first five sessions of each unit, problem–solution instruction was delivered, with problems that varied only in their cover stories. A poster listing the steps of the solution method was displayed during the tutoring session. In Session 1, RA tutors used concrete objects to address the underlying concepts and structural features for the problem type. Together with the students, RA tutors worked several examples and, as they referred to the poster

and the concrete objects, explained why and how each step of the solution method had been applied in the examples. Next, students responded frequently to questions as they worked two to four problems together with their tutor. Beginning in Session 2, students then completed one problem independently, which the tutor reviewed and scored.

Sessions 6–9 were designed to broaden schemas, with each problem varying the cover story and one of two transfer features: different question or irrelevant information. RA tutors first taught the meaning of the word *transfer* and then used a poster, *Transfer: To Move*, to teach the two transfer features. Although five bulleted types of transfer features were included on the poster for continuity with the whole-class sessions, the two covered in tutoring sessions were bolded and in larger font for emphasis. In Session 6, RA tutors explained the poster, illustrating both superficial features with working examples. In Sessions 6–9, students still completed a problem independently, although this was never a transfer problem.

For Cohort 1, AR tutored students were randomly assigned to SBI without self-regulated learning strategies (see preceding description) or to SBI with self-regulated learning strategies. Self-regulated learning strategies were designed to help students become more metacognitively, motivationally, and behaviorally active in their own learning (cf. De Corte, Verschaffel, & Eynde, 2000; Zimmerman, 1995). The strategies incorporated the following components. First, RA tutors reminded students to stay on task by working hard, listening carefully, and following directions. RA tutors set timers for three irregular intervals throughout the session (the timing for each session was standardized across tutors); when the timer sounded, each student earned a point if all students in the group were on task. If any student was off task, no student received a point. Second, students received up to three points per session for accurate work, with the task for which accuracy was rewarded varied across sessions (but standardized across RA tutors). Third, students completed one problem, called the Hot Math problem of the day. This problem was scored on a 20-point scale by the RA tutors, according to a specific rubric; students were encouraged to participate in the scoring and to meet or beat their previous day's score. Fourth, following the Hot Math problem of the day, students shaded their Hot Math thermometers with the number of points they had earned over the session. Fifth, students used their Hot Math thermometers to set a goal for next day. Sixth, students were awarded stickers for each point. At the end of each session, students totaled their points and noted their totals on a game board.

In Year 2, self-regulated learning strategies were incorporated into both experimental tutoring-level conditions as part of the regular treatment, with students earning "dollars" instead of stickers and having the opportunity to spend dollars at the Hot Math store each week or to save their dollars. Both tutoring conditions used these strengthened self-regulated learning strategies, but with or without drill-and-practice warm-ups at the beginning of each lesson. These warm-ups were designed to build fluency with a foundational skill necessary for the specific unit (e.g., repeated addition for the stepping-up problem type). Thus, AR tutored students were randomly assigned to SBI with strengthened self-regulated learning strategies or SBI with strengthened self-regulated learning strategies plus warm-ups. All students in Cohorts 3 and 4 who were randomly assigned to tutoring received SBI with strengthened self-regulated learning strategies.

*Delivery.* RA tutors had responsibility for tutoring (for Cohorts 1 and 2, each RA tutored groups in both SBI tutoring conditions). Consistent with an RTI prevention system, tutoring occurred in addition to, not as a substitute for, classroom math instruction and was conducted by someone other than the classroom teacher, in this case the RA tutor. Also, as with an RTI prevention system, students within a given tutoring group were not necessarily from the same classroom.

*Treatment fidelity.* Prior to the first delivery of each session in each condition, RA tutors agreed on the essential information in the script and made a checklist of points. Each tutoring session was audiotaped. At the study's end, four research assistants independently listened to tapes while completing the checklist to identify the percentage of points addressed. We sampled tapes so that, within conditions, RA tutors, groups, and session numbers were sampled equitably. For each of 64 small tutoring groups, 20% of sessions were sampled (seven or eight tapes distributed equally across the four units). Intercooder agreement, calculated on 20% of the sampled tapes, was 96.4%. The mean percentage of points addressed across all units was 98.12 ( $SD = 1.28$ ).

### Research Assistants

Across the 4 years of the study, the typical research assistant was 1 to 2 years beyond undergraduate education, studying for a graduate degree in education, special education, counseling, or education policy. The majority of research assistants worked for the project for 1 year, with six RA teachers remaining for more than 1 year and three RA tutors working for more than 1 year. During each year of the study, two full-time project coordinators, typically with bachelor's- or master's-level degrees outside of education, also served as RA teachers and RA tutors. Each year, five or six RA teachers and another five or six RA tutors were needed. The same research assistants did not conduct classroom SBI and tutoring sessions.

For classroom SBI, a typical RA teacher was responsible for the same four classrooms across 16 weeks of intervention, teaching each classroom two times each week, usually two classes per day, and alternating days for a given classroom. For example, an RA teacher might teach Classrooms 1 and 2 on Monday, Classrooms 3 and 4 on Tuesday, Classrooms 1 and 2 again on Wednesday, and Classrooms 3 and 4 again on Thursday.

Each RA tutor was responsible for one or two control classrooms for general problem-solving strategies during the first 3 weeks and then for three or four tutoring groups during the next 13 weeks. A typical RA tutor taught the same three or four tutoring groups across the 13 weeks, three times per week. The RA tutor's schedule was usually the same on each of the three tutoring days, with students typically receiving tutoring on Tuesday, Wednesday, and Thursday. Tutoring groups were determined on the basis of preferred schedules provided by classroom teachers.

To train research assistants, we conducted the following activities. In an introductory meeting, all research assistants were trained on research ethics and procedures, including professional behaviors in schools. Then research assistants were trained for their specific role within the project (RA teacher or RA tutor) in one full-day session. Research assistants were introduced to the project and its goals, assigned roles (RA teacher or RA tutor), and provided with instruction, demonstrations, and scripted materials

to study. They were paired to practice the treatment. Then, they conducted one lesson for a project coordinator and were judged on a point-by-point system for fidelity to treatment. A research assistant who achieved 95% fidelity was considered reliable. A research assistant who scored lower than 95% fidelity was coached on points he or she missed, asked to practice more, and then rerated at a later time on another lesson. At weekly meetings, project staff met separately with RA teachers and with RA tutors for problem-solving sessions. At the beginning of each unit, a 3-hr training sessions was conducted to orient research assistants and to distribute supporting materials. In addition, all sessions were audiotaped, and the audiotapes were used in part to monitor research assistants for fidelity throughout treatment. Research assistants were provided with written corrective feedback and provided with one-to-one retraining as needed.

### Measures

*Math problem solving.* We used three measures of problem solving. These measures all sampled novel problems (i.e., never seen before or used for instruction). They incorporated the four targeted problem types, but the measures differed from each other in terms of transfer distance in relation to problems used for problem-solution instruction. We refer to the three measures as immediate transfer, near transfer, and far transfer (increasing numbers signify greater transfer distance).

The immediate-transfer measure incorporated novel problems in the same format as the problems used for problem-solution instruction. The near-transfer measure incorporated novel problems that varied from the problems used for problem-solution instruction in terms of one or more of the transfer features addressed in SBI: unfamiliar vocabulary, different question, irrelevant information, or combination of problem types. The far-transfer measure, which was designed to mirror real-life problems, varied from the problems used for instruction in multiple ways. The far-transfer measure was formatted to look like a commercial, standardized test; it presented a multiparagraph narrative with four questions; some of the information needed to answer the question was removed from the multiparagraph narrative and placed in figures or question stems; it contained multiple pieces of numeric and narrative irrelevant information; it provided opportunities for students to formulate decisions; it combined all four problem types; and it varied all four SBI transfer features.

None of the cover stories had been used for instruction. Each measure had two alternate forms; problems on both forms required the same operations and presented text with the same number/length of words. Immediate-transfer alternate forms incorporated the same numbers; near-transfer alternate forms incorporated the same numbers; and far-transfer alternate forms used similar numbers. In half the classes in each condition, we used Form A at pretest and Form B at posttest; in the other half, forms were reversed.

The immediate-transfer measure comprised 10 word problems, equally representing the problem-solving units. Across the 10 problems, the maximum score was 44. For this sample, Cronbach's alpha was .84 at pretest and .95 at posttest; concurrent validity with WJ III Applied Problems (Woodcock et al., 2001) was .56 at pretest and .42 at posttest. Interscorer agreement, computed on

20% of protocols by two independent scorers who were unaware of the purpose of the study, was .983 at pretest and .960 at posttest.

The near-transfer measure comprised nine problems: a shopping list problem with a novel format (information shown in bulleted format, with a selection rather than an open-ended response format); a shopping list problem with a novel question (asking for money left at the end); a buying bags problem with a different keyword (*packages* instead of *bags*); a buying bags problem with a novel question (comparing prices of two packaging options); a half problem with unfamiliar vocabulary (*share equally* instead of *half*); a pictograph problem with a novel question (asking for money left at the end); a pictograph problem with a novel question (comparing quantities at the end); a problem with irrelevant information that combined a buying bags problem with a pictograph problem and combined novel vocabulary with a novel question; and a problem with irrelevant information that combined a shopping list problem with a buying bags problem and combined a novel format with a novel question. For this sample, across items, the maximum score was 79. Cronbach's alpha was .87 at pretest and .96 at posttest; concurrent validity with WJ III Applied Problems (Woodcock et al., 2001) was .52 at pretest and .40 at posttest. Interscorer agreement, computed on 20% of protocols by two independent scorers who were unaware of the purpose of the study, was .985 at pretest and .973 at posttest.

The far-transfer measure simultaneously assessed transfer of all four problem types and the four transfer features addressed in SBI. Also, to decrease association between the task and classroom or tutoring SBI, the far-transfer measure was formatted to look like a commercial test (printed with a formal cover, on green paper, with photographs and graphics interspersed throughout the test booklet). Two assessments were constructed as alternate forms: Although the context of the problem situations differed, the structure of the problem situation and the questions were identical, and the problem solutions and reading demands were equivalent.

Performance was scored according to a rubric with four dimensions: conceptual underpinnings, computational applications, problem-solving strategies, and communicative value. The original rubric (Kansas Board of Education, 1991) scored responses on a 6-point scale. To enhance reliability, we awarded points on a finer basis (e.g., the problem-solving strategies score included points for finding relevant information, accumulating to a total, showing all computation, working the answer in distinct multiple parts, labeling at least half of the multiple parts, and labeling work with monetary and operation signs). Across the four questions and four scoring dimensions, the maximum score is 72. For this sample, Cronbach's alpha was .91 at pretest and .94 at posttest; concurrent validity with WJ III Applied Problems (Woodcock et al., 2001) was .47 at pretest and .61 at posttest. Interscorer agreement, computed on 20% of protocols by two independent scorers who were unaware of the purpose of the study, was .987 at pretest and .949 at posttest. Given the deleterious effects of student unfamiliarity with performance assessments (L. S. Fuchs et al., 2000), research assistants delivered a 45-min lesson on test taking strategies before pre- and posttesting in all conditions. (The mean score across immediate, near, and far transfer correlated .62 with WJ III Applied Problems, Woodcock et al., 2001, at pretest and .57 at posttest.)

*Math applications.* The 60-item WJ III Applied Problems (Woodcock et al., 2001) measures skill in analyzing and solving

practical math problems. The tester orally presents items involving counting, telling time or temperature, and problem solving. Testing is discontinued after six consecutive errors. The score is the number of correct items. As reported by McGrew and Woodcock (2001), the 1-year test-retest reliability is .85; the ratio of true score variance to observed variance is .88–.91. Coefficient alpha on this sample was .85.

### *Data Collection*

Trained research assistants administered the three problem-solving measures in whole-class arrangement. For the immediate-transfer and near-transfer measures, research assistants read aloud each item and provided students with time to complete their work before progressing to the next item. For the far-transfer measure, research assistants read the entire assessment and reread portions to individuals, at their request, as they worked. Trained research assistants administered the WJ III Applied Problems individually, outside the classroom in a quiet location in the school. All pre-testing occurred during the 3 weeks before treatment; posttesting occurred during the 3 weeks following treatment. To avoid having familiar research assistants prompting awareness that SBI might apply, students were unfamiliar with their testers. The RA teachers and RA tutors used scripted sets of directions to administer the three whole-class problem-solving measures. In many cases, the RA teachers and RA tutors could identify study conditions, but given the whole-class, scripted administration, it seems unlikely that testers could have influenced performance. An entirely different pool of research assistants administered individual WJ III Applied Problems, so these testers had no way of knowing the study conditions in which students had participated.

### *Data Analysis*

We converted scores on the three problem-solving measures to percentage correct so that performance on the three measures could be compared. To examine how much of the total variance in improvement on the three problem-solving measures was explained by the clustering of children in classrooms and in tutoring groups, we estimated variance components with SAS PROC MIXED (Littell, Milliken, Stroup, Wolfinger, & Schabenger, 2006). The resulting intraclass correlations showed that the effect for classroom clustering explained 16.10% of the variance ( $p < .001$ ) and that the effect for tutoring-group clustering explained 4.10% of the variance ( $p = .006$ ). We therefore incorporated each as a random effect into our model, which also included four fixed effects: one within-subjects factor (problem-solving measure) and three between-subjects factors (classroom condition, tutoring condition, and cohort). To assess pretreatment comparability, we fit a full model that included all main effects, two-way, three-way, and four-way interactions as well as estimating the impact of classroom as a random effects factor.

To index learning as a function of study condition, we used improvement on the three problem-solving measures. (Fitting a model with improvement scores produces the same effects as would considering the interaction between test occasion [pre- vs. posttest] and study conditions. We opted for improvement scores because their interpretation is more straightforward.) In this full model, the variance component for tutoring group decreased to

zero (indicating that all of the variance associated with tutoring group clusters was explained in the model). Therefore, we fixed the random effects of tutoring group to zero and also eliminated from the final model all higher order interactions that were not statistically significant. To follow up significant effects, we Bonferroni corrected  $p$  values by the number of follow-up tests we ran for that significant effect. We subtracted the difference between improvement means and then divided by the pooled standard deviation of the improvement/square root of  $2(1 - r_{xy})$  to compute effect sizes (ESs; Glass, McGaw, & Smith, 1981). To examine the effects of the classroom and tutoring tiers of SBI prevention on the prevalence of math difficulty, we designated difficulty as performing below the 16th percentile on WJ III Applied Problems at the end of intervention and applied chi-square analyses.

## Results

See Table 3 for means and standard deviations by classroom condition and by tutoring condition (for means and standard deviations by classroom condition, tutoring condition, and cohort, contact Lynn S. Fuchs). See Table 3 for rates of difficulty status by classroom and tutoring conditions and for ESs.

### *Pretreatment Comparability on Math Problem Solving*

See Table 3 for means and standard deviations. There were no significant effects for classroom condition,  $F(1, 274) = 0.06$ ,  $p = .811$ , or for cohort,  $F(3, 3274) = 0.14$ ,  $p = .938$ . As expected, there was a significant effect for tutoring condition,  $F(2, 3274) = 236.75$ ,  $p < .001$ , with NAR students performing higher than each of the two AR tutoring groups (both  $p < .001$ ), which performed comparably to each other ( $p = .587$ ). Also, there was a significant effect for measure,  $F(2, 3274) = 27.43$ ,  $p < .001$ . Across classroom conditions, across tutoring conditions, and across cohorts, students performed higher on immediate transfer than on near transfer, performed higher on immediate transfer than on far transfer ( $p < .001$ ), but performed higher on far transfer than on near transfer ( $p < .001$ ). Students scored higher on far than on near transfer at pretreatment because far transfer incorporated a greater variety of problem types, some of which were simpler than the problem types on near transfer. Neither of these main effects threatens the internal validity of the study. (Moreover, as shown later, improvement on far transfer was harder to effect, supporting its far-transfer designation.) The two-way interactions were as follows: for the Classroom Condition  $\times$  Tutoring Condition interaction,  $F(2, 3274) = 0.22$ ,  $p < .799$ ; for the Classroom Condition  $\times$  Measure interaction,  $F(2, 3274) = 0.21$ ,  $p < .814$ ; for the Tutoring Condition  $\times$  Measure interaction,  $F(4, 3274) = 28.75$ ,  $p < .001$ ; for the Classroom Condition  $\times$  Cohort interaction,  $F(3, 3274) = 0.52$ ,  $p < .666$ ; for the Tutoring Condition  $\times$  Cohort interaction,  $F(6, 3274) = 0.68$ ,  $p < .663$ ; and for the Measure  $\times$  Cohort interaction,  $F(6, 3274) = 2.76$ ,  $p = .011$ . For Cohorts 1, 2, and 4, students performed higher on immediate transfer than on near transfer (all  $p < .001$ ), performed higher on immediate transfer than on far transfer (all  $p < .001$ ), but performed higher on far transfer than on near transfer (all  $ps < .001$ ; except for Cohort 1,  $p = .005$ ). By contrast, the third cohort scored comparably on near and far transfer ( $p = .022$ ; with immediate-transfer scores higher than both other measures, as was the case for the other three

cohorts, both  $ps < .001$ ). Because neither classroom nor tutoring conditions were involved in this interaction, it does not threaten the validity of the study. None of the three- or four-way interactions was significant.

### *Math Problem-Solving Learning as a Function of Prevention Conditions*

See Table 3 for means and standard deviations; see Table 4 for ESs. We first consider the primary question addressed in the present study: Is tutoring more effective with validated classroom instruction? Then, we consider other effects involving treatment. Finally, we list results for the remaining effects, which are of less interest.

*Is tutoring more effective with validated classroom instruction?* The interaction between classroom condition and tutoring condition was significant,  $F(2, 3320) = 24.33, p < .001$ . We pursued this interaction in three ways. First, exclusively with AR students, we tested the difference between tutoring with and without validated classroom instruction directly; this was significant ( $p < .001$ ;  $ES = 1.34$ ). Second, again focusing exclusively on AR learners, we contrasted the difference between tutored and control students who received conventional classroom instruction ( $ES = 1.18$ ) versus the difference between tutored and control students who received validated SBI classroom instruction ( $ES = 1.13$ ). This was not significant ( $p = .308$ ), suggesting that the effects of two tiers of prevention are additive, not synergistic. Finally, we considered the pattern of improvement between NAR versus AR students as a function of tutoring condition within each classroom treatment. With classroom control, improvement of NAR students and AR control students was comparable ( $p = .011$ ); NAR students improved less than AR tutored students ( $p < .001$ ); and AR tutored students improved more than AR controls ( $p < .001$ ). By contrast, when students received classroom SBI, NAR students outgrew AR control students ( $p < .001$ ); AR tutored students continued to outgrow AR controls ( $p < .001$ ); and the improvement of NAR and AR tutored students was comparable ( $p = .108$ ).

*Interactions with problem-solving measure.* The main effect for classroom condition was significant,  $F(1, 3320) = 160.32, p < .001$ . Classroom condition did, however, interact significantly with measure,  $F(2, 3320) = 176.37, p < .001$ . The effect of classroom condition was significant on immediate transfer ( $p < .001$ ) and on near transfer ( $p < .001$ ), but not on far transfer ( $p = .495$ ).

The main effect of tutoring condition was also significant,  $F(2, 3320) = 51.67, p < .001$ . There was, however, a significant interaction between tutoring condition and measure,  $F(4, 3320) = 27.61, p < .001$ . On immediate transfer, NAR students outgrew AR control students ( $p < .001$ ). Of importance, however, AR tutored students outgrew AR control students ( $p < .001$ ), and most impressively, AR tutored students also outgrew NAR students ( $p < .001$ ). On near transfer, although NAR and the AR tutored students again outgrew AR control students (both  $ps < .001$ ), the improvement of the NAR and the AR tutored students was comparable on this measure ( $p = .813$ ). A different pattern emerged on the far-transfer measure. Although the contrast between AR tutored students and AR control students only approached significance ( $p < .043$ ), the NAR students outgrew both AR groups of learners (both  $ps < .001$ ).

*Interaction between tutoring and cohort.* Tutoring also interacted significantly with cohort,  $F(6, 3320) = 3.45, p = .002$ . In the follow-up to this interaction, we focused exclusively on AR students by looking at the effect of receiving versus not receiving tutoring for Cohorts 2, 3, and 4 and comparing each to the effect for Cohort 1. This is interesting because with tutoring SBI, none of the students in Cohort 1 had the strengthened version of self-regulated learning strategies, and although all of Cohort 2 had the strengthened version of self-regulated learning strategies, half of this cohort had the warm-up drill and practice activities. By contrast, all of the SBI tutored students in Cohorts 3 and 4 received the strengthened version of self-regulated learning strategies without warm-up activities. In line with this instructional design feature, the contrast between tutored Cohorts 1 and 2 was not significant ( $p = .194$ ; ESs comparing AR tutored against AR control were

Table 4  
*Effect Sizes on Improvement Scores by Classroom Condition and Tutoring Condition (Across, Cohorts)*

NAR vs. AR tutored	-0.54	0.11	0.44	-0.05
NAR vs. AR control	0.53	0.86	0.64	0.73
AR tutored vs. AR control	1.34	1.09	0.37	1.17
Across-tutoring conditions: SBI vs. control	1.90	1.73	0.36	1.51

*Note.* A positive value indicates that the first condition named was higher. A negative value indicates that the second condition named was higher. NAR = not at risk; AR = at risk; SBI = schema-broadening instruction.

0.60 for Cohort 1 vs. 0.97 for Cohort 2), but the contrast between Cohorts 1 and 3 was significant ( $p < .001$ ; ESs comparing AR tutored against AR control were 0.60 for Cohort 1 vs. 1.86 for Cohort 3), the contrast and between Cohorts 1 and 4 was also significant ( $p = .002$ ; ESs comparing AR tutored against AR control were 0.60 for Cohort 1 vs. 1.57 for Cohort 4).

*Remaining effects.* The measure effect was significant,  $F(2, 3320) = 219.97, p < .001$ . As expected, across classroom conditions, tutoring conditions, and cohorts, improvement on immediate transfer exceeded improvement on near transfer ( $p < .001$ ); improvement on immediate transfer exceeded improvement on far transfer ( $p < .001$ ); and improvement on near transfer exceeded improvement on far transfer ( $p < .001$ ). The cohort effect was not significant,  $F(1, 3320) = 0.43, p < .733$  (indicating that across classroom conditions, tutoring conditions, and measures, improvement of the four cohorts was comparable).

Math Difficulty as a Function of Prevention Conditions

See Table 5 for math difficulty by classroom and tutoring conditions. Chi-square analyses indicated no relation between math difficulty status and classroom condition,  $\chi^2(1, N = 1141) = 0.18, p = .672$ . To examine the relation between math difficulty status and tutoring condition (where we had three levels: NAR, AR control, and AR tutored), we allocated one degree of freedom to the contrast between NAR versus AR (control and tutored), which revealed a significant relation:  $\chi^2(1, N = 1141) = 104.27, p < .001$ . We allocated the other degree of freedom to the contrast between the two AR groups, which also revealed a significant relation:  $\chi^2(1, N = 243) = 7.08, p = .008$ .

We then estimated overall prevalence of math difficulty as a function of whether AR students received tutoring. To estimate overall prevalence without tutoring, we did the following calculation: (the number of NAR students identified as having math difficulty plus the number of AR control students identified as having math difficulty plus [the proportion of AR control students identified as having math difficulty times the proportion of AR tutored students]) divided by the number of students in the 89 classrooms who completed the study ( $n = 1,141$ ). We added the proportion of AR control students identified as having math difficulty times the proportion of AR tutored students, because we

wanted to include the base rate of expected math difficulty in the tutored group if they had not been tutored. In a similar way, to estimate overall prevalence with tutoring, we did the following calculation: (the number of NAR students identified as having math difficulty plus the number of AR tutored students identified as having math difficulty plus [the proportion of AR tutored students identified as having math difficulty times the proportion of AR control students]) divided by the number of students in the 89 classrooms who completed the study ( $n = 1141$ ). Here, we added the proportion of AR tutored students identified as having math difficulty times the proportion of AR control students, because we wanted to include the rate of math difficulty expected in the control group if they had been tutored. Without tutoring, we estimate a math difficulty prevalence rate of 6.8%; with tutoring, we estimate a rate of 3.9%.

Discussion

The primary purpose of this large-scale randomized field trial was to assess the effects of third-grade small-group tutoring with and without validated classroom instruction on AR students' math problem solving and their learning relative to NAR peers. The issue of how tutoring interacts with classroom instruction among students at risk for poor learning outcomes is important for designing efficient and effective RTI prevention systems. If tutoring is differentially efficacious when combined with validated classroom instruction, then both tiers are critical, and classroom instruction needs to be designed deliberately with AR students in mind, even when they receive tutoring. By contrast, if tutoring promotes comparable outcomes regardless of the classroom instructional context, then findings would set the stage for research on whether tutoring might occur as a replacement for, rather than as a supplement to, classroom instruction. This would make RTI prevention systems logistically easier and more efficient, thus facilitating scheduling and permitting resources to be infused at the tutoring tier. In addition, when considering tutoring efficacy as a function of the classroom context, it is important not only to compare the response of AR students who do and do not receive tutoring, but also to contrast the learning of AR students against their NAR peers. This has not been addressed in prior work.

Therefore, in the present study, we randomly assigned classrooms to validated or conventional instruction, designated incoming risk status (NAR vs. AR), and within classroom conditions, randomly assigned AR students to receive or not receive tutoring. This allowed us to compare the learning of AR students (with one, two, or no tiers of SBI) and NAR students (with and without validated classroom prevention). We considered this an efficacy study, in which the key question was whether interventions had their intended effects when they were actually implemented. Toward that end, we relied on research assistants to implement SBI classroom instruction and SBI tutoring. We note, however, that within most RTI models, someone other than the classroom teacher implements Tier 2 tutoring; therefore, the use of research assistants to conduct tutoring does not compromise external validity.

Results revealed an interaction between the two tiers of prevention. Of importance, tutoring was significantly and substantially more effective when it occurred in combination with validated classroom instruction than when the tutoring occurred with con-

Table 5  
Difficulty Status by Classroom Condition and Tutoring Condition (Across Cohorts)

Tutoring condition for groups with MD <sup>a</sup>	Classroom condition					
	Control		SBI		Across	
	<i>n</i>	%	<i>n</i>	%	<i>n</i>	%
NAR	2	0.6	11	1.8	13	1.4
AR control	8	28.5	13	25.5	21	26.6
AR tutoring	7	12.5	14	12.9	21	12.8
Across	17	4.5	38	5.0	55	4.8

Note. SBI = schema-broadening instruction; MD = math difficulty; NAR = not at risk; AR = at risk.  
<sup>a</sup>Final Woodcock-Johnson Applied Problems score was below the 16th percentile.

ventional classroom instruction ( $ES = 1.34$ ). This suggests that two tiers are better than one tier of prevention and indicates the importance of providing AR students with validated instruction in the classroom and then supplementing that instruction with high-quality tutoring. In the present study, the two tiers of instruction were closely aligned, both addressing the same types of word problems at the same time and both relying on the same theoretical (SBI) and operational (Hot Math) approach to instruction. It is possible that when the two tiers of instruction are less well aligned, as is often the case, results would differ. Moreover, it is possible that alignment of Tier 1 and Tier 2 instructional content may differ as a function of academic domain. Consequently, we emphasize that future studies should assess the added value of validated classroom instruction that is more and less aligned with tutoring for different academic content. At the same time, even with closely aligned instruction at the two tiers of the prevention system, our results showed that the advantage for AR tutored students over AR control students was comparable with ( $ESs = 1.18$ ) and without ( $ES = 1.13$ ) validated classroom instruction. Thus, the effects of two tiers of prevention appear to be additive rather than synergistic.

It is also interesting to consider the effects of one versus two tiers of validated prevention by comparing the performance of AR students against NAR peers (at least in the area within which intervention occurred, i.e., in math problem solving). When contrasting AR tutored students' learning with that of NAR peers, two tiers of prevention again appear to have made a difference, but in an unanticipated way. With only one tier of prevention (i.e., tutoring for AR students combined with conventional classroom instruction for AR and NAR students), AR tutored students improved more than NAR students, by an impressive half a standard deviation. Therefore, when AR and NAR students received conventional classroom math problem-solving instruction, with AR students receiving tutoring, the achievement gap between AR and NAR students narrowed substantially (at preintervention,  $ES = 1.09$ , with the mean difference between AR and NAR students representing 2.80 standard errors of measurement; at postintervention,  $ES = 0.13$ , with the mean difference between AR and NAR students less than 1 standard error of measurement). This unexpected finding shows the power of SBI tutoring to effect strong learning among AR students, who initially performed substantially below NAR classmates. It also suggests that classroom teachers require guidance about how to promote math problem-solving learning. On the other hand, with two tiers of prevention (i.e., validated classroom instruction and tutoring for AR students combined with validated classroom instruction for NAR students), AR tutored and NAR students achieved comparably ( $ES = 0.14$ ). When AR and NAR students received validated classroom math problem-solving instruction, with AR students also receiving a second tier of tutoring, the achievement gap between AR and NAR students remained sizeable and comparable (at preintervention,  $ES = 1.29$ , with the mean difference between AR and NAR students representing 3.11 standard errors of measurement; at postintervention,  $ES = 0.72$ , with the mean difference between AR and NAR students representing 2.71 standard errors of measurement).

In terms of the contrast between AR control and NAR students, NAR students consistently improved more than AR controls, with an  $ES$  of 0.37 without classroom SBI and an  $ES$  of 1.17 with

classroom SBI. This was expected. When AR and NAR students received the same single tier of validated classroom math problem-solving instruction, without AR students receiving a second tier of preventive tutoring, the achievement gap between AR and NAR students grew (at preintervention,  $ES = 1.30$ , with the mean difference between AR and NAR students representing 3.28 standard errors of measurement; at postintervention,  $ES = 1.55$ , with the mean difference between AR and NAR students representing 5.95 standard errors of measurement; hence, the gap between AR and NAR students at pre- versus postintervention increased by 2.69 standard errors of measurement). The differential effect of validated classroom practices, favoring NAR over AR students, has been documented in prior work (e.g., L. S. Fuchs et al., 1997).

Together, findings indicate that intensive instruction, in the form of preventative tutoring, is essential for AR students. Without it, the gap between AR and NAR students continues to widen, even when NAR students suffer the disappointing effects of conventional classroom instruction in math problem solving. Accordingly, results highlight the importance of validated problem-solving instruction in the Tier 1 classroom and suggest that tutoring occur as a supplement to, not a replacement for, classroom instruction. This is the case for AR students: When they receive tutoring combined with validated classroom instruction, their learning exceeds that of students who receive tutoring without validated classroom instruction—by a practically important  $ES$  of 1.34 standard deviations. At the same time, the importance of validated classroom instruction is also clear for NAR students, whose problem-solving learning is superior with validated classroom SBI. Readers should take note, however, that when AR students receive two tiers of validated instruction while their NAR classmates receive validated classroom instruction, the AR students' performance gap is unlikely to narrow. We also caution that these results cannot be generalized beyond third grade, beyond math problem solving, and beyond instruction that is closely aligned across tiers. Additional research exploring these issues at other grades and in other academic areas and research testing the effects with and without instructional alignment are warranted.

This need for additional studies at other grades and in other areas is illustrated by comparing our results to those of Gilbert et al. (2007). Working with reading in first grade, Gilbert et al. showed that validated classroom instruction did not contribute to tutoring efficacy. At least two differences between our study and Gilbert et al.'s study help explain the inconsistency of findings. First, because Gilbert et al. tutored students at instructional levels that were substantially below classmates' levels, classroom teachers and tutors did not work on identical skills at the same time (as was the case in the present study). Second, Gilbert et al.'s AR sample had already proven unresponsive to the fall semester's validated classroom instruction; therefore, it is not surprising that second-semester Tier 2 tutoring was not differentially effective when combined with Tier 1 validated instruction. By contrast, we used a more typical RTI method for identifying students for risk and for tutoring: initial performance on predictors of outcome.

In addition to studying the contribution of validated classroom instruction to the efficacy of tutoring in terms of math problem-solving outcomes, we also examined the prevalence of mathematics difficulty with and without validated classroom instruction and with and without tutoring. We operationalized math difficulty with a widely used tool for identifying math disability in the schools.

Also, WJ III Applied Problems (Woodcock et al., 2001) is broader than our math problem-solving outcome measures, assessing skill in analyzing and solving practical math problems that involve counting and telling time or temperature, as well as problem solving. In addition, we selected a relatively stringent cutpoint (the 15th percentile) for designating difficulty, and we note that students were not identified for participation and/or designated as AR with this measure. Even so, the prevalence of math difficulty was clearly associated with tutoring. Although AR students were, as expected, disproportionately represented in the math difficulty category compared with NAR students, AR tutored students were significantly and dramatically less likely than AR controls to be designated as having math difficulty at the end of the study. That is, tutoring cut the proportion of students with math difficulty in half: from 26.6% of AR control students (or 6.8% of the general population) to 12.8% of AR tutored students (or 3.9% of the general population). At the same time, math difficulty status was not associated with classroom condition, even when looking exclusively at AR students who received validated classroom SBI versus conventional classroom instruction. Thus, it appears that tutoring, not validated classroom instruction, is the active agent that reduces math difficulty status for AR students. This suggests that tutoring is the tier that moves student ranking around the cutpoints used to designate disability and corroborates the strong need for tutoring among the population of learners at risk for poor math problem-solving learning.

Four additional findings, although not the primary purpose of the present study, also merit discussion. First, results strengthen previous work (L. S. Fuchs, Fuchs, et al., 2003b; L. S. Fuchs, Fuchs, Prentice, et al., 2004) showing that Hot Math SBI enhances mathematical problem solving. Across the three problem-solving measures and across tutoring conditions, the ES favoring classroom SBI over conventional teachers' mathematics problem-solving instruction was 1.51 standard deviations. Thus, SBI was superior to teachers' conventional instruction, even when the problem types addressed within SBI were selected to correspond with the schools' (i.e., the control group's) curriculum. Given that the researchers designed SBI with considerable effort over years, it may seem unsurprising that SBI was more effective than conventional classroom instruction. Therefore, it is important to note that L. S. Fuchs, Fuchs, et al. (2003b) demonstrated that SBI makes a sizeable contribution beyond researcher-designed problem-solution instruction, which does not teach students to broaden schemas for transfer to novel problems. We therefore conclude that effects are due to schema-broadening instruction and not simply to researcher-designed problem-solution instruction.

Second, findings demonstrate the efficacy of SBI for tutoring AR students on problem types that extend beyond total, difference, and change relationships addressed in prior work (L. S. Fuchs et al., 2008; Jitendra et al., 1998, 2002; Jitendra & Hoff, 1996; Xin et al., 2005). By contrast, the problem types addressed in the present study involve multiple quantities of more than one kind of item, halving quantities, step-up functions, and pictograph problems, with emphasis on multistep problem solving, combining problem types, and ignoring irrelevant information. Across the three problem-solving measures and across classroom SBI and control conditions, the ES favoring SBI tutoring over control among AR learners exceeded 1 standard deviation ( $ES = 1.17$ ), even though

two thirds of untutored (control) AR students received SBI at the classroom level. Few validated tutoring protocols exist at the second tier of RTI multitier prevention systems. Results provide an option for schools to use within their RTI systems for math problem solving on problem types appropriate for third grade.

Third, the interaction between tutoring condition and cohort suggests that for AR learners, systematic motivation may be important for promoting learning within small-group tutoring. For Cohort 1, although tutoring incorporated self-regulated learning strategies, the motivation system within those self-regulated learning strategies was weak. By contrast, for Cohorts 3 and 4, tutoring incorporated a strengthened motivation system within self-regulated learning strategies, which relied on tangible reinforcers for listening carefully, following directions, paying attention, working hard, and producing accurate work. Accordingly, the differences in outcome for Cohort 1 versus Cohort 3 and for Cohort 1 versus Cohort 4 were statistically significant, with ESs of 1.86 and 1.57, respectively. (This strengthened motivation system was first incorporated with the Cohort 2 tutored sample; however, half of the Cohort 2 tutored sample also received a warm-up drill and practice, which proved problematic. The difference in learning outcome for Cohort 1 vs. Cohort 2 was not statistically significant, even though the ES was a sizeable 0.60.) These findings suggest the need for systematic motivation systems to address task persistence deficits among AR learners (Deci & Chandler, 1986; Deci & Ryan, 1985; Garber & Seligman, 1980). This may be particularly relevant when solving mathematical word problems, which requires meta-cognition and persistence in the face of challenge (De Corte et al., 2000). Causal-comparative studies (e.g., Lester & Garofalo, 1982; Schoenfeld, 1992; Silver, Branca, & Adams, 1980) illustrate how self-regulation differs between weak and skilled problem solvers: Experts spend more time analyzing problems before initiating solutions, reflect more frequently on their problem solving, and alter their approach more flexibly. Motivation to think through challenging tasks and to persist with the task even when initial efforts are not successful may be critical, and future research should address this question more directly.

Fourth, results illustrate the difficulty of enhancing students' real-life problem solving, as revealed with a significant interaction between classroom condition and problem-solving measure. Learning was significantly stronger for classroom SBI compared to classroom control on immediate- and near-transfer measures, both of which included entirely novel math problems, with near-transfer problems extending well beyond what had been directly taught within SBI. The ESs for the immediate- and near-transfer measures, respectively, were 1.90 and 1.73. On far transfer, however, the effect was not statistically significant. The far-transfer measure, designed to mirror real-life problems, varied from the problems used for instruction in multiple ways. This measure presented a multi-paragraph narrative with four questions; some of the information needed to answer the question was removed from the multi-paragraph narrative and placed in figures or question stems; it contained multiple pieces of irrelevant numeric and narrative information; it provided opportunities for students to formulate decisions; it combined all four problem types; and it varied all four SBI transfer features. Given the transfer distance involved in the far-transfer measure, the ES of 0.36 is notable, especially because effects were demonstrated with relatively

young students for whom schema-induction competence (e.g., Chen, 1999) and problem-solving competence (Chen, 1999; Durnin et al., 1997; Foxman et al., 1991, cited in Boaler, 1993; Larkin, 1989) have proven hard to effect. Present findings do, however, suggest the need for additional research to examine how to strengthen real-life problem solving.

In a similar way, an interaction between problem-solving measure and tutoring condition was also documented. On immediate transfer, AR tutored students improved more than NAR students ( $ES = 0.54$ ), and both groups grew more than the AR control group ( $ES = 1.34$  for AR tutored and  $0.53$  for NAR). On near transfer, the improvement of NAR and AR tutored students was comparable ( $ES = 0.11$ ), but again both groups grew better than AR controls ( $ES = 0.86$  for NAR and  $1.09$  for AR tutored). Only on far transfer did the improvement of NAR students exceed that of AR tutored students ( $ES = 0.44$ ), and the improvement of AR tutored versus AR control students only approached statistical significance ( $p = .043$ ;  $ES = 0.37$ ). Again, given the transfer distance involved in the far-transfer measure and the sizeable deficits the AR students brought to the tutoring table, the  $ES$  of  $0.37$  favoring AR tutored over AR control students appears promising, but additional work exploring methods for promoting real-life problem solving is required.

In summary, relying on a randomized field trial while accounting for the nested structure of the data, the present study provides evidence for the efficacy of SBI for classroom use and for tutoring use in promoting superior math problem solving with AR and NAR students. Moreover, in terms of RTI prevention systems, results indicate that two tiers of validated instruction are better than one tier but that the effects of two tiers are additive, not synergistic. Findings also illustrate the disappointing efficacy of conventional math problem-solving instruction and the need for improved methods to teach math problem solving in general education classrooms. SBI appears to represent one potentially strong method for achieving that goal. At the same time, as shown previously (e.g., Bransford & Schwartz, 1999; A. L. Brown et al., 1992; Durnin et al., 1997; Foxman et al., 1991, cited in Boaler, 1993; Larkin, 1989; Mayer et al., 1999), findings once again corroborate the difficulty of promoting far transfer, in this study operationalized as real-life problem solving. Additional studies exploring methods for enhancing far transfer are warranted. Given the promising  $ES$ s on this study's far-transfer measure, researchers might consider marrying SBI with other approaches toward that end.

Before closing, we note that research assistants, not teachers, delivered classroom and tutoring SBI, with close monitoring of the fidelity of implementation. Therefore, this investigation qualifies as an efficacy study, not an effectiveness study. That is, findings demonstrate that SBI promotes superior outcomes at the classroom and tutoring prevention tiers under conditions that ensure strong SBI implementation. The present study does not address issues of effectiveness, that is, whether SBI effects can be realized when implemented by teachers (for classroom SBI) and school-based support staff (for tutoring SBI), and does not address issues about how to scale up Hot Math SBI. Given the demonstration of Hot Math SBI efficacy in the present study, research focused on issues of effectiveness and scaling up appear warranted.

### Members of Underrepresented Groups: Reviewers for Journal Manuscripts Wanted

If you are interested in reviewing manuscripts for APA journals, the APA Publications and Communications Board would like to invite your participation. Manuscript reviewers are vital to the publications process. As a reviewer, you would gain valuable experience in publishing. The P&C Board is particularly interested in encouraging members of underrepresented groups to participate more in this process.

If you are interested in reviewing manuscripts, please write to the address below. Please note the following important points:

- To be selected as a reviewer, you must have published articles in peer-reviewed journals. The experience of publishing provides a reviewer with the basis for preparing a thorough, objective review.
- To be selected, it is critical to be a regular reader of the five to six empirical journals that are most central to the area or journal for which you would like to review. Current knowledge of recently published research provides a reviewer with the knowledge base to evaluate a new submission within the context of existing research.
- To select the appropriate reviewers for each manuscript, the editor needs detailed information. Please include with your letter your vita. In the letter, please identify which APA journal(s) you are interested in, and describe your area of expertise. Be as specific as possible. For example, "social psychology" is not sufficient—you would need to specify "social cognition" or "attitude change" as well.
- Reviewing a manuscript takes time (1-4 hours per manuscript reviewed). If you are selected to review a manuscript, be prepared to invest the necessary time to evaluate the manuscript thoroughly.

Write to Journals Office, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

# Social Comparison and Big-Fish–Little-Pond Effects on Self-Concept and Other Self-Belief Constructs: Role of Generalized and Specific Others

Herbert W. Marsh  
University of Oxford

Ulrich Trautwein and Oliver Lüdtke  
Max Planck Institute for Human Development

Olaf Köller  
Humboldt University

Two studies integrate the big-fish–little-pond effect (BFLPE; negative effects of class-average achievement on academic self-concept, ASC), which is based upon educational psychological research, with related social psychological research that is based on social comparison theory. Critical distinctions are the nature of the social comparison processes that are based on generalized-other (class- or school-average) or individual (target comparison classmate) comparisons, and the nature of self-belief constructs that invoke normative (social comparison) or absolute frames of reference. In a large cross-national study (26 countries; 3,851 schools; 103,558 students), school-average ability negatively affected ASC but had little effect on 4 other self-belief constructs that did not invoke social comparison processes. In Study 2 (64 classes; 764 students), 2 sources of social comparison information (class-average achievement and achievement of an individually selected target comparison classmate) each had distinct, substantial negative effects on agency self-beliefs that invoked social comparison processes but not on metacognitive responses that did not invoke these processes.

**Keywords:** big-fish–little-pond effect, self-concept, social comparison theory, multilevel modeling, cross-national comparisons

The phenomenon of the self is widely accepted as an important universal aspect of being human and central to understanding the quality of human existence (Bandura, 2006; Branden, 1994; Bruner, 1996; Marsh & Craven, 2006; Pajares & Schunk, 2005). Positive self-beliefs are at the heart of the recent emphasis on a positive psychology. However, self-concept theory emphasizes that perceptions of the self cannot be adequately understood if the role of frames of reference is ignored. The same objective characteristics and accomplishments can lead to disparate self-concepts depending on the frames of reference or standards of comparison that individuals use to evaluate themselves, and these self-beliefs have important implications for future choice, performance, and behaviors.

Marsh and colleagues (see Marsh, 1991, 2007; Marsh & Craven, 2002; Marsh & Hau, 2003) proposed the big-fish–little-pond effect

(BFLPE) to encapsulate frame-of-reference effects in educational settings. In the BFLPE model, it is hypothesized that students compare their own academic ability with that of their classmates and use this social comparison information as one basis for forming their own academic self-concept (ASC). A negative BFLPE (a contrast effect) occurs when students have lower ASCs when they compare themselves to more able students and they have higher ASCs when they compare themselves with less able students. Consistent with theoretical predictions and a growing emphasis on the multidimensionality of self-concept, this research shows that the BFLPE is very specific to ASC; self-esteem and nonacademic components of self-concept are relatively unrelated to both individual- and group-average academic achievement.

## BFLPE: Effect Sizes, Social Comparison, and Item Wording

Herbert W. Marsh, Department of Educational Studies, University of Oxford, Oxford, England; Ulrich Trautwein and Oliver Lüdtke, Center for Educational Research, Max Planck Institute for Human Development, Berlin, Germany; Olaf Köller, Institute for Educational Progress, Humboldt University, Berlin, Germany.

Work on the present investigation was conducted, in part, while Herbert W. Marsh was a visiting scholar at the Center for Educational Research at the Max Planck Institute for Human Development in Berlin and was supported in part by the University of Oxford and the Max Planck Institute.

Correspondence concerning this article should be addressed to Herbert W. Marsh, Department of Educational Studies, University of Oxford, 15 Norham Gardens, Oxford OX2 6PY, United Kingdom. E-mail: herb.marsh@education.ox.ac.uk

How well do these BFLPE findings, which are so robust in relation to ASC, generalize to other academic self-belief constructs such as agency, control, persistence, efficacy, metacognition and, specifically, self-efficacy? (For more discussion, see Bong & Skaalvik, 2003; Marsh, 1993; Skaalvik & Bong, 2003; Skaalvik & Rankin, 1995; Skaalvik & Skaalvik, 2002.) In particular, Marsh (1993) argued that frame-of-reference effects are directly implicated in ASC responses as individuals use the performances of others to establish frames of reference for evaluating their own performances. In contrast, little emphasis has been placed on the frames of reference that participants use to evaluate their performances in specific self-efficacy research. Bandura (1986), for

example, noted that self-esteem and self-concept—but not self-efficacy—are partly determined by “how well one’s behavior matches personal standards of worthiness” (p. 410). In specific self-efficacy judgments, the focus of assessment is on the individual’s capabilities in relation to the specific criterion items presented, and so the influence of frame of reference effects is minimized. Thus, for example, when students are shown example math test items and asked the probability of correctly answering such items, their responses are based on an absolute criterion that does not require them to compare their own performances with those of other students (also see Bong & Skaalvik, 2003).

For present purposes we distinguish between self-belief constructs, such as ASC, that (implicitly or explicitly) invoke normative comparisons and those, such as self-efficacy, that do not. The relevance of this distinction has been highlighted in a series of studies testing the internal/external frame of reference (I/E) model (Marsh, Walker, & Debus, 1991; also see Skaalvik & Rankin, 1995; Skaalvik & Skaalvik, 2002). According to the I/E model, students use an *external* (social comparison) frame of reference such as that posited in the BFLPE but also use an *internal* (ipsative-like) frame of reference in which students compare their own performance in one school subject (e.g., mathematics) with their own performance in other school subjects (e.g., English). Marsh et al. found clear support for frame-of-reference effects consistent with the internal comparison process for self-concept responses but not for self-efficacy responses. In exploring the implications of their results, Marsh et al. suggested that test-specific self-efficacy ratings severely truncated the operation of frame-of-reference effects and the evaluative responses to self-perceptions. For example, in judging the likelihood of correctly answering a test item on a math test, students have little need to compare their performance in one subject with their own performances in other subjects such as English (internal comparison) or with the performances of other students in mathematics (external comparison). Furthermore, a response of 80% likelihood of successfully answering a particular math problem does not indicate whether the student considers this to be a good or bad outcome. However, Marsh et al. also noted that some measures purporting to measure self-efficacy are based on stimuli likely to invoke social comparisons with other students (e.g., “I’m certain I can do an excellent job on assignments and tests,” where the term *excellent* might imply a comparison with the work of others). Hence, the empirically demonstrated distinction between self-concept and self-efficacy responses is likely to depend on the nature and wording of the items rather than on the label assigned to the construct.

A similar distinction can be made in terms of *postdictions* of performance, student judgments of their success following performance but before they know the outcome of their performance. Self-regulated learners are skillful at monitoring their learning process, including, for example, planning and self-efficacy prior to performance, attention control and self-regulation during performance, and appropriate self-reflection following performance (Zimmerman, 1998). Judgments of learning (Isaacson & Fujita, 2006; Nelson & Narens, 1994; Tobias & Everson, 2002) are an aspect of metacognitive knowledge monitoring that occurs during or after learning and are relevant to future planning and self-regulation. Thus, Isaacson and Fujita (2006; also see Hacker, Bol, Horgan, & Rakow, 2000) asked students to predict their test results

after completing the test but before they knew the test outcome—postdictions of performance. More accurate postdictions were associated with higher levels of achievement, and high-achieving students gave increasingly more accurate postdictions over time. Like self-efficacy ratings, postdicted performance can be assessed in relation to absolute standards of performance (e.g., number of test items correctly answered) rather than in relation to normative frames of reference that invoke a social comparison process.

There now seems to be clear empirical support for the normative and absolute distinction in the wording of items in different self-belief constructs and its influence upon the internal frame-of-reference effect—how a student’s self-beliefs in any one school subject are influenced by the same student’s performances in other school subjects. This previous research, however, has not extended the evaluation of this distinction to the external (social comparison) process posited in the BFLPE. Furthermore, although clearly supporting the distinction between specific self-efficacy and self-concept responses, this previous research has not, more fully, evaluated suggestions by Marsh et al. (1991) that this distinction has broader relevance to a range of self-belief items that vary in terms of this normative and absolute distinction. Hence, an overarching purpose of the present investigation is to explore the generalizability of the BFLPE to a variety of self-belief constructs associated with competence, agency, control, persistence, and test-performance expectations—as well as self-concept—and to relate variations in the size of the BFLPE in different constructs to this normative–absolute distinction.

#### Alternative Sources of Social Comparison Information: The Generalized Versus Specific Other

A major distinction between most social comparison theory (SCT) studies in social psychological research and BFLPE studies in educational psychology is the source of social comparison information. In the BFLPE, students are posited to use a generalized other as an implicit basis of comparison. This generalized other is operationalized as the mean performance level of other students in the same class or school. The process is implicit in that students are not explicitly instructed to make comparisons with other students. In social psychological research based on SCT, the focus is usually on a single target comparison person whom the participant explicitly chooses (e.g., Blanton, Buunk, Gibbons, & Kuyper, 1999; Diener & Fujita, 1997; Huguet, Dumas, Monteil, & Genestoux, 2001; Seaton et al., in press; Suls & Wheeler, 2000; Wheeler, 1966; Wood, 1989, 1996). The process is explicit in that the participant is explicitly instructed to choose a target comparison person. Implicit in this process is the assumption that students may use any one or a combination of a wide variety of different strategies in the selection of a target person (e.g., choosing someone more able because the student wants to identify and be more like the target person; choosing a target who is more able in order to learn how to perform the task better; choosing a target person who is less able in order for the student to look good and to protect the student’s self-concept; choosing a target person who is of similar ability to evaluate how well the student did in a particular situation; etc., also see Wood, 1989). In order to allow students as much flexibility as possible in choosing the target person, researchers typically give students little or no instruction on how to choose the target person. There is surprisingly little research jux-

taping results based on implicit comparisons with a generalized other emphasized in BFLPE studies and explicit comparisons based on a specific target comparison person emphasized in SCT research, even though the approaches are based on apparently similar theoretical rationales.

Because Festinger's early research that led to his development of SCT emphasized group processes, it is not surprising that he also emphasized this notion of a generalized other as a basis of normative comparisons between the self and a group—how individuals use groups to evaluate their abilities and opinions (Festinger, 1954; also see Suls & Wheeler, 2000). What we find surprising is that this historically important construct of generalized other has had so little emphasis in more recent SCT research that has focused more on variations of what became known as the rank-order paradigm, the choice of specific target individuals as a basis of comparison, the comparison of upward and downward comparison strategies, and how these strategies satisfy competing needs.

In BFLPE research, positive effects of attending schools in which the school-average ability is high (e.g., assimilation effects associated with reflected glory or pride associated with attending an academically selective school that leads to higher ASCs) has been elusive (see Lüdtke, Köller, Marsh, & Trautwein, 2005; Trautwein, Lüdtke, Marsh, Köller, & Baumert, 2006). Even when positive assimilation effects have been found, they are overshadowed by a counterbalancing negative contrast effect so that the net effect of attending academically selective schools on ASC is negative (Marsh, Kong, & Hau, 2000). Similarly, based on their review of SCT research, Buckingham and Alicke (2002) noted that while factors such as task relevance, similarity to the comparison target, cognitive load, and perceived control may be relevant,

people generally evaluate themselves more positively when the comparison information reflects favorably (i.e., following downward comparisons) rather than unfavorably (i.e., following upward comparisons) on their characteristics and abilities, especially when they receive direct feedback regarding their own and others' behavioral or performance outcomes. (p. 1117)

However, unlike BFLPE research in which there is consistent support for the negative effects of upward comparisons, the theoretical predictions and empirical results are not so clear in SCT studies. In particular, when participants are able to choose a target person with whom to compare, upward comparisons sometimes result in assimilation rather than contrast, leading Major, Testa, and Bylsma (Major, Testa, and Bylsma, 1991, p. 238) and many others to describe social comparisons as a "double-edged sword." An important focus of much of this SCT research has been the strategies that individuals use to select comparison targets (e.g., upward and downward comparison strategies) to maximize competing needs. Thus, upward evaluations might provide a basis of identification with more accomplished target persons, even though such target persons are likely to provide a more demanding basis of comparison for self-evaluations, leading to feelings of inferiority. Nevertheless, when asked to choose target persons with whom to compare themselves, participants typically choose targets who are similar or slightly better than themselves (i.e., upward rather than downward; see Blanton et al., 1999; Huguet et al., 2001; Suls & Wheeler, 2000; Wheeler, 1966).

Whereas the emphasis on generalized others in BFLPE studies may be a reasonable assumption within an imposed social comparison paradigm in educational settings (Diener & Fujita, 1997), more research is needed to test the generalizability of this effect over different sources of social comparison information such as that provided by individual target comparison persons chosen by students in free-choice situations. Furthermore, the uses of generalized and specific comparison targets are not mutually exclusive. Individuals might simultaneously evaluate their performances in relation to both the performances of specific target individuals selected in ways that have been considered in SCT research and in relation to some generalized performance based on a group-average performance, as posited in BFLPE research.

Reuman (1989) conducted one of the few studies to juxtapose a generalized and specific other. Consistent with the BFLPE, he found that ability grouping (i.e., assigning students to low-, medium-, or high-ability classes rather than to more heterogeneous, mixed-ability classes) produced lower ASCs for high-ability children and higher ASCs for low-ability children. When students were asked to compare their test scores with those of a classmate and whether the selected classmate was more or less able, ability grouping was associated with systematic differences in the perceived ability of the comparison classmate. Children from high-ability classes were more likely to select classmates with higher abilities than their own (upward comparison), and children from low-ability classes were more likely to select classmates with lower abilities than their own (downward comparisons). However, Reuman did not evaluate whether the direction of comparison affected ASC and whether this effect of comparison direction was independent of the average ability levels of the different classes.

It is also relevant to note that the distinction between normative and absolute frames of reference that is one focus of the present investigation has not been widely considered or integrated into SCT. However, Smith and Arnelsson (2000) made a similar distinction in relation to the possible referents of ability appraisal in SCT: ability relative to absolute standards demanded of a task (e.g., how quickly I can run 1 km—an absolute judgment that does not require relativistic responses); ability relative to specific others (as emphasized in SCT); and ability relative to a reference group (a response in relation to a generalized other as emphasized in BFLPE studies). Smith and Arnelsson noted that in order to most accurately estimate ability relative to a group, participants should use an aggregate index of group performance (as in the class-average achievement in BFLPE studies), and this preference for class-average performance was demonstrated by Suls and Tesch (1978).

### The Present Investigation

In the present investigation we conducted two studies to test the generalizability of the BFLPE in relation to different self-belief constructs posited to invoke different frames of reference and to different sources of social comparison information (also see Trautwein & Lüdtke, 2005). Study 1 was based on a large cross-national sample in which we evaluated the effects of school-average achievement on ASC and a variety of other academic self-beliefs that varied in relation to which frame of reference they invoked: normative or absolute. Study 2 was based on a large

representative sample of German high school students and included self-belief constructs that varied in terms of the absolute and normative distinction that was the focus of Study 1, but also in terms of different sources of social comparison information based on generalized others (class-average achievement) and specific others (selection of a specific target comparison classmate). In both studies we evaluated the generalizability of the BFLPE based on ASC to other academic self-belief constructs and tested our prediction that BFLPEs would be systematically larger for constructs that invoke a normative or social comparison frame of reference than for constructs that invoke an absolute frame of reference.

In Study 2, we sought to integrate the distinctions made in BFLPE and SCT studies in relation to sources of social comparison information. This is apparently the first BFLPE study to simultaneously evaluate the combined effects of upward comparisons based on a generalized other (as operationalized by class-average achievement in BFLPE studies) and a specific other (as operationalized by free choice of a specific target comparison person in SCT studies). Although we posited that the effect of upward comparisons in relation to both sources of social comparison information would be negative (negative effects of class-average achievement and upward comparison choice), the theoretical and empirical support for these predictions is much stronger for generalized others (from BFLPE studies) than for specific others (from SCT studies). Of particular relevance are the questions of the extent to which the two sources of social comparison make independent contributions to self-belief constructs when both are considered simultaneously and whether the size (or even the direction of assimilation instead of contrast) of either changes substantially when the other is considered.

### Study 1

Study 1 was a large cross-cultural test of the generalizability of the BFLPE based on nationally representative samples of students from 26 countries. We evaluated the generalizability of the BFLPE based on ASCs (Marsh & Hau, 2003) across a range of other self-belief factors. For ASC, consistent with the BFLPE, we predicted that (a) the effect of individual student achievement would be positive and not vary substantially from country to country and (b) the effect of school-average achievement would be negative and not vary substantially from country to country. The central research question in Study 1 was how well these results based on ASC generalize to four additional self-belief constructs: general self-efficacy, control expectations, control strategies, and effort persistence. Each of these self-belief constructs has a rich theoretical and empirical basis that led to their selection by expert panels of the Organisation for Economic Cooperation and Development (OECD) as being among the best, most useful, and psychometrically strongest constructs in educational psychology. (For a detailed discussion of these constructs and the basis of their selection, see Marsh, Hau, Artelt, Baumert, & Peschar, 2006; see wording of the items in Appendix A.) However, in the present investigation, we focused particularly on our observation that each of these constructs is based on responses to items that invoke a more absolute frame of reference than the ASC responses, leading us to predict that the BFLPE will be smaller for these constructs than for ASC.

However, because of the nature and wording of these other self-belief constructs (Appendix A), we anticipated that there would be some normative frame-of-reference effects resulting in a negative effect of school-average ability. Thus, for example, in order to respond to the general self-efficacy item "I'm confident I can do an excellent job on assignments and tests," students would be likely to use the other students in their educational context as a basis of comparison in forming judgments about what constitutes excellent performance, their level of confidence (i.e., "How confident am I relative to other students?"), and their underlying ability that was a probable basis of their confidence. Hence, this general self-efficacy item is different from specific self-efficacy items considered in other research (see earlier discussion of Marsh et al., 1991) in which the criterion of success was explicit in the item and not dependent on comparisons with an external, normative standard (e.g., other students in the class or school). Similar observations apply to items from the conceptually similar control expectation scale (e.g., "If I decide not to get any bad grades, I can really do it"). The implied use of other students as a basis of comparison is less clear for items from the effort persistence ("When studying, I keep working even if the material is difficult") and control strategy ("When I study, I force myself to check to see if I remember what I have learned") in that these items do not necessarily require comparisons with other students.

### Method

*Data source and sample.* Study 1 was based on the Programme for International Student Assessment (PISA) database compiled by the OECD that consists of responses by nationally representative samples of approximately 4,000 15-year-olds collected in 32 countries in the year 2000 (for a description of the database and variables, see OECD, 2001a, 2001b, 2003; also see Marsh, Hau, et al., 2006). The PISA database was collected in response to the need for internationally comparable evidence of student performance and related competencies within a common framework that was internationally agreed upon. Selection of the measures was made on the basis of advice from substantive and statistical expert panels and the results from extensive pilot studies. In many cases (see Marsh, Hau, et al., 2006) the selection of items used to represent a particular scale was a subset of the items from a widely used instrument. Thus, for example, the ASC items (Appendix A) selected for inclusion in the PISA study were a subset of the 10 items in the Self Description Questionnaire II (Marsh, 1990, 1992), selected on the basis of those with the best psychometric properties in previous research and on the subsequent pilot studies conducted by the OECD (see Marsh, Hau, et al., 2006). Substantial efforts and resources were devoted to achieving cultural and linguistic breadth in the assessment materials, stringent quality assurance mechanisms were applied in the translation of materials into different languages, and data were collected under independently supervised test conditions.

Paper-and-pencil assessments consisted of a combination of multiple-choice items and written responses. While all students completed some reading assessment items, which were the focus of the 2000 data collection, only random samples of students completed mathematics or science assessments. In addition, countries were given the option of collecting materials on the Student Approaches to Learning instrument (Marsh, Hau, et al., 2006) that

included all self-belief scales that were the focus of the present investigation. Twenty-six of 32 countries administered this additional survey. Evaluations of responses to these scales based on this database demonstrated good psychometric properties (a well-defined factor structure based on multiple-group confirmatory factor analyses across the 26 countries, reliability, and validity in relation to academic achievement; see Marsh, Hau, et al., 2006). Coefficient alpha estimates of reliability for the five scales considered here are (see Appendix A): ASC (.78), self-efficacy (.75), control expectations (.75), control strategies (.76), and effort-persistence (.78).

Study 1 was based on students who completed the Student Approaches to Learning instrument and standardized academic achievement tests that were developed specifically for PISA. In preliminary analyses, confirmatory factor analyses of responses to items representing these five scales indicated that the five a priori factors were well-defined in that factor loadings were consistently high and the goodness of fit for the a priori factor structure provided an excellent fit to the data (see Appendix B).

Due to the nature of the PISA project, nine versions of the achievement tests were administered that contained different combinations of verbal, mathematics, and science test items. Owing to the focus of the PISA study, all students completed at least some verbal test items, whereas only about half of the students completed math and science tests. Using test-equating procedures based on item response theory, scores based on each version of the various achievement tests were put onto a comparable scale. For present purposes, a total achievement test score was obtained by taking an average score for all the achievement test scores available for each student. As recommended in the database documentation (OECD, 2001a, 2001b), analyses were conducted using sample weights to obtain unbiased estimates of population parameters. For purposes of the present investigation, the effective sample size for each country was set to be equal to the number of cases for that country prior to weighting, so that the weighted sample size was the same as the unweighted sample size (i.e., the average weight across all cases was 1.0; see Marsh & Hau, 2003).

*Statistical analysis.* In most studies conducted in school settings, individual student characteristics are confounded with classroom or school characteristics because individuals are not randomly assigned to groups. This clustering effect introduces problems related to appropriate levels of analysis, aggregation bias, and heterogeneity of regression (Goldstein, 2003; Raudenbush & Bryk, 2002). In the present investigation, for example, the meaning of a variable at the student level does not necessarily bear any straightforward relation to its meaning at the school level. The negative BFLPE is a dramatic example of this problem—achievement at the individual student level is positively related to ASC, whereas achievement at the school level is negatively related to ASC. The juxtaposition of the effects of individual and school-average achievement is inherently a multilevel issue that cannot be represented adequately at either the individual or the school level. A detailed presentation of multilevel modeling (also known as hierarchical linear modeling) is beyond the scope of the present investigation and is available elsewhere (e.g., Goldstein, 2003; Raudenbush & Bryk, 2002; Snijders & Bosker, 1999). All models reported here are random-intercept models estimated by iterative generalized least squares (using MLwiN, version 2.2; Rasbash, Steele, Browne, & Prosser, 2004). Consistent with the PISA de-

sign, we considered a three-level multilevel model in which students (Level 1) were nested within schools (Level 2) and schools were nested within countries (Level 3). In order to enhance interpretations of the results, we standardized (*z*-scored) all variables to have  $M = 0$ ,  $SD = 1$  across the entire sample (see Marsh & Rowe, 1996; also see Aiken & West, 1991; Raudenbush & Bryk, 2002). School-average measures of achievement were determined by taking the average of achievement scores for students in each school (but not restandardizing these scores so that individual student and school-average achievement scores were in the same metric).

In Study 1, individual student achievement and school-average achievement were related to the ASC and other self-belief constructs. We estimated fixed and random effects associated with the variables of interest (see Table 1). The fixed effects consisted of the main effects of individual student achievement and school-average achievement and a constant term (which is approximately zero because of the use of standardized variables and, thus, is of little practical interest). Random effects consisted of intercept terms associated with each level of the model, indicating the extent to which intercepts varied from country to country (Level 3), from school to school (Level 2), and from student to student (Level 1). These terms reflect the amount of unexplained (residual) variance at each of the three levels. In addition, the effects of individual achievement were allowed to be random at both the school and the country level, providing an indication of how much the effect of individual achievement on ASC varied from country to country and from school to school. Finally, the effects of school-average achievement were also allowed to be random at the country level, providing an indication of how much the effect of school-average achievement on ASC varies from country to country.

## Results and Discussion

In Model M1 (Table 1), we tested the basic BFLPE for ASC. Consistent with previous research (Marsh & Hau, 2003), there was a substantial positive effect (.38) of individual student achievement on ASC. Students who scored 1 *SD* above the mean of the academic achievement test on average scored .38 *SD* above the mean of the ASC scale. Of particular relevance to tests of the BFLPE, there was a substantial negative effect (−.20) of school-average achievement on ASC. On average, students attending schools in which the average achievement level was 1 *SD* above the mean achievement level (in the metric of the individual student achievement test scores) scored .2 *SD* below the mean of the ASC scale. Although the effects of individual and school-average achievement on ASC varied significantly from country to country, due in part to the extremely large sample size, this variation was very small (both residual variance components were .01). In summary, the results provide strong support for the generalizability of the BFLPE across the 26 countries included in this OECD database.

In Models M2–M5 (Table 1) we tested the generalizability of the BFLPE found with ASC to four other self-belief constructs. Consistent with a priori predictions, the negative effects of school-average achievements (the BFLPE) were systematically less negative for all four of these constructs (−.08 to .03) than that observed with ASC (−.20). In fact, whereas the negative effects of school-average achievement were small but statistically significant ( $p < .05$ ) and negative for self-efficacy (−.08) and control expectations

( $-.06$ ), the effects were not statistically significant for control strategies ( $.03$ ) and effort persistence ( $-.01$ ). These results clearly support predictions that the BFLPE would be smaller for these other self-belief constructs than for ASC.

Although differences among the sizes of the effects of the school-average achievement for the four additional self-belief constructs were small, it is interesting to speculate on the nature of these differences. Previous research (Marsh et al., 1991) found that frame-of-reference effects (based on a given student's performance in other school subjects) were much smaller for specific self-efficacy measures than for self-concept. Although we know of no direct comparisons of the generalizability of this distinction to social comparison frame-of-reference effects posited in the BFLPE, it might be expected that the negative effect of school-average achievement would be less negative for efficacy than for other self-belief scales. However, there are reasons why this expectation was not warranted in the present study. In particular, this previous research was based on test-specific self-efficacy measures in which students were asked to estimate the probability of correctly answering items like those shown to them—a task that did not require them to compare their relative abilities in different school subjects or, relevant to the present investigation, to compare their own ability levels with those of their classmates. In this respect, the generalized self-efficacy measure from the PISA study was quite different.

Indeed, as suggested earlier, the self-efficacy and control expectation items (see Appendix A) both might invoke students to make comparisons with other students in forming their response, whereas items from the control strategies and effort persistence scales apparently do not. This suggests that the lack of frame-of-reference effects associated with different self-belief constructs might be a function of the precise nature of the items used to measure each construct as well as inherent differences in content

of the constructs. Whereas the efficacy responses were apparently less subject to frame-of-reference effects than were the self-concept responses, it is also relevant to note that academic achievement was systematically more strongly related to ASC ( $.38$ ) than to any of the other self-belief constructs, and that the two self-belief constructs that did have significant frame-of-reference effects were more strongly related to achievement ( $.30$ , self-efficacy;  $.27$ , control expectations) than were the other two for which frame-of-reference effects were not significant ( $.19$ , control strategies;  $.15$ , effort persistence). Hence, not surprisingly, social comparison information typically provides a useful basis for forming accurate self-appraisals. In summary, the results of Study 1 clearly support a priori predictions about differences in the sizes of the BFLPE for ASC and the other self-belief constructs.

## Study 2

In Study 2 we extended findings from Study 1 and previous research in two ways.

1. Predictions about the lack of frame-of-reference effects in Study 2 were based on a metacognitive measure, math-test-specific performance postdictions (MTSPP), in which students estimated the number of items that they had correctly answered immediately after taking a test. While the results of Study 1 clearly demonstrated that the negative effects associated with the BFLPE were systematically smaller for a variety of self-belief constructs than for ASC, there was no test-specific measure in which measures were based on such a clearly absolute scale as the number of questions students predicted that they had correctly answered. (Note that performance expectations used here clearly differed from the traditional test-specific self-efficacy measures like those used by Marsh et al., 1991, in that expectations were in relation to a test already completed. However, the two measures are similar in

Table 1  
*Study 1: Generalizability of the Big-Fish–Little-Pond Effect Across Five Constructs*

Variables	M1 Academic Self	M2 Self-Efficacy	M3 Control Expectation	M4 Control Strategies	M5 Effort Persistence
	<i>b</i> ( <i>SE</i> )	<i>b</i> ( <i>SE</i> )	<i>b</i> ( <i>SE</i> )	<i>b</i> ( <i>SE</i> )	<i>b</i> ( <i>SE</i> )
Fixed effects					
Level 1: Individual Achievement	.38 (.024)*	.30 (.018)*	.27 (.020)*	.19 (.014)*	.15 (.017)*
Level 2: School-Avg Achievement	-.20 (.019)*	-.08 (.023)*	-.06 (.022)*	.03 (.020)*	-.01 (.021)
Residual variance components					
Level 3: Country					
Intercept	.09 (.050)	.05 (.023)*	.06 (.021)*	.09 (.026)*	.05 (.019)*
Individual Achievement	.01 (.004)*	.01 (.002)*	.01 (.002)*	.01 (.001)*	.01 (.002)*
School-Avg Achievement	.01 (.002)*	.01 (.005)*	.01 (.004)*	.01 (.003)*	.01 (.004)*
Level 2: School					
Intercept	.02 (.002)*	.02 (.003)*	.02 (.002)*	.02 (.003)*	.02 (.003)*
Individual Achievement	.01 (.001)*	.01 (.001)*	.01 (.001)*	.01 (.001)*	.01 (.001)*
Level 1					
Residual	.78 (.027)*	.87 (.027)*	.89 (.024)*	.86 (.025)*	.82 (.025)*

Note. All outcome and predictor variables were standardized ( $M = 0$ ,  $SD = 1$ ) at the individual student level. In each analysis, individual achievement and school-average achievement were related to one of the five self-report factors. All parameter estimates are statistically significant when they differ from zero by more than two standard errors (*SEs*).

\*  $p < .05$

that the response scale—the number of correctly answered items—is clearly an absolute scale rather than a normative scale that invokes social comparisons).

Although previous research has demonstrated the relevance of this absolute–normative comparison distinction in relation to frame-of-reference effects based on the juxtaposition of performances in different school subjects by the same student (an internal comparison; e.g., Marsh et al., 1991), we sought to determine whether these conclusions generalize to fundamentally different frame-of-reference effects based on the juxtaposition between performance by a particular student and those of his or her classmates (an external comparison). In particular, we were not aware of tests of this distinction in any previous BFLPE or SCT studies. In addition to this MTSP measure we also evaluated the BFLPE in relation to a measure of math agency that is based on generalized items (e.g., “I’m pretty smart in things that concern mathematics”) that invoke social comparison processes like those self-concept responses. On the basis of the nature of these two constructs, previous research, and the results of Study 1, we predicted that the BFLPE based on class-average math achievement would be systematically more negative for math agency than for MTSP, and that these frame-of-reference effects would be much smaller (or nonsignificant) for MTSP.

2. We compared results based on a generalized other (operationalized as class-average achievement as in BFLPE studies) and a specific other (operationalized as direction of comparison with a freely chosen target comparison classmate as in SCT studies) separately. We also examined the combined effects of both these sources of social comparison information. While contrast effects have consistently been found in BFLPE studies in which comparisons are implicit, the results have not been so consistent in other social comparison research in which participants have been explicitly instructed to choose a target person and have had considerable freedom in the strategies that they have used to make this choice (e.g., Buunk & Gibbons, 2000; Diener & Fujita, 1997). Perhaps reflecting this distinction, Stapel and Suls (2004) noted that implicit comparisons result in contrast effects (negative effects of upward comparison), but explicit comparisons can produce assimilation effects (positive effects of upward comparison). This distinction is apparently relevant in that comparison with a generalized other or class average in BFLPE research is implicit, whereas SCT studies are typically based on explicit comparisons. Hence this methodological distinction between comparisons involving (implicit) generalized others and an (explicit) chosen target comparison classmate is theoretically important. We expect both sources of social comparison information (class-average achievement and upward comparisons) to have negative effects on the more generalized measure of agency, consistent with the BFLPE, but the basis for predictions for the chosen target comparison classmate has less empirical support from previous research. However, we also predict that both sources of information will have less negative (or no) effect on MTSP.

## Method

*Sample.* The sample consisted of 736 students (49.8% girls) who had a mean age of 13.8 years ( $SD = .67$ ) enrolled in a representative sample of 64 mathematics classes from one large German state. The sample was representative of the state in terms

of school type: Hauptschule, 22.7%; Realschule, 24.6%; Gymnasium, 36.3%; and Comprehensive, 16.4%. Data were collected in the second half of the seventh grade. Because in this state students change to secondary school after Grade 4 and almost all students remain in intact classes throughout the secondary level, these students had already been taught mathematics in their secondary school classroom for more than 2 years prior to the time of the study. The test materials were administered by trained research assistants. The data used in Study 2 were part of a larger study on historic changes in school achievement with a total of 1,452 students. In all classes, the students were randomly allocated to two different testing conditions. Only half of the students were asked to answer the comparison task (see below), and these 736 students considered here constituted a random sample of the total group.

*Mathematics achievement.* The items constituting the math achievement test were taken from previous national and international studies, in particular the First and Second International Mathematics Study (Husén, 1967; Robitaille & Garden, 1989) and an investigation conducted at the Max Planck Institute for Human Development (cf. Baumert, Roeder, Sang, & Schmitz, 1986). Various content areas—arithmetic, geometry, elementary statistics, and algebra—were covered, and the curricular validity of all items had been assessed beforehand by curriculum experts. The reliability of the 46-item test was .85 (using the Kuder–Richardson formula 20).

*Self-belief scales.* Two measures of self-beliefs were used. To assess MTSP, students were asked to estimate the number of items on the mathematics test that they had solved correctly after they had completed the test (i.e., a postdiction). To assess math agency, we adapted three items from the Agency Beliefs: Ability Scale from the Control, Agency, and Means–Ends Interview (CAMI; T. D. Little, Oettingen, Stetsenko, & Baltes, 1995; see Skinner, Zimmer-Gembeck, & Connell, 1998) to the mathematics domain using a 4-point (*disagree–agree*) response scale (see Appendix A for wording of the items). The coefficient alpha estimate of reliability for agency responses based on results from the present investigation was .68.

*Comparison target choice and comparison direction.* It is important to emphasize that both the students’ freedom of choice in selecting a target comparison classmate and the direction of the comparison were critical components of this construct. After having finished their mathematics tests and postdicting the number of correctly answered items, students were instructed to nominate the student whose test booklet they would like to compare with their results. Following the procedure typically used in this area of research (e.g., Reuman, 1989; Swallow & Kuiper, 1992; also see Wood, 1989), students were not instructed as to how to make this selection or given any specific criteria to use in this decision. Thus, as would be the case outside of an experimental setting, students had complete freedom in choosing their comparison target. In particular, they were free to choose a target comparison classmate who was more able (upward comparison), less able (downward comparison), or equally able. Because this is the typical approach used in social psychological research (see Wood, 1996), it was important for us to use a similar procedure in the present investigation in which we sought to juxtapose these results with those based on the class-average achievement measure used in BFLPE.

After choosing a target comparison classmate, students were then asked to compare their typical mathematics performance with that of their chosen target comparison classmate. Students were asked to indicate "Is this student in mathematics (a) better than you? (b) not as good as you? (c) similar in achievement level?" A majority of students chose target comparison classmates perceived as better (55%), whereas 30% and 15% of the students chose target comparison students perceived to be not as good as and similar to them. In this respect the results were like those found in other social comparison research (see Suls & Wheeler, 2000) in that there was a tendency toward upward comparison (selecting a more able student), although there were also substantial numbers who chose comparison targets who were of similar or lower ability.

Three scores were constructed to represent these responses: upward comparison (upward = 1, else = 0), downward comparison (downward = 1, else = 0), and upward-downward comparison (upward = 1, equal = 0, downward = -1). Because the third score was completely determined by the first two (i.e., they were completely multicollinear), the purpose of using these alternative representations was to determine which one or combination of two scores provided the best and most parsimonious representation of this variable.

**Statistical analyses.** The statistical analyses conducted in Study 2 were similar to those in Study 1. Specifically, we conducted a multilevel analysis to assess the effects of individual student math achievement, class-average math achievement, and comparison direction on MTSPPE and math agency. As in Study 1, in order to enhance the interpretability of the effects, we standardized all independent and dependent variables ( $M = 0$ ,  $SD = 1$ ). Academic achievement was aggregated at the class level to form class-average achievement based on standardized test scores of individual students but was not restandardized so that class-average achievement was measured on the same metric as individual student achievement tests. All reported models are random-intercept models estimated by iterative generalized least squares (using MLwiN, version 2.2; Rasbash et al., 2004). Missing data represent a potentially serious methodological problem in many empirical studies. Whereas the amount of missing data (6%)

was not large, there is growing recognition of the inappropriateness of traditional approaches to missing data such as listwise and pairwise deletion of missing data (e.g., Enders, 2006; R. J. A. Little & Rubin, 1987; Schafer, 1997). In Study 2 we used NORM software (version 2.03, see Schafer & Graham, 2002) to impute missing values. The NORM software uses an expectation-maximization approach to estimate the variance-covariance matrix on which basis missing values are imputed.

### Results and Discussion

**Math agency.** The results of Model 1 for agency (Table 2) provide clear support of the typical BFLPE. In particular, there was a substantial positive predictive effect of individual student achievement and a substantial negative predictive effect of class-average achievement. In Model 2 for agency (Table 2) we tested the same model with the upward comparison variable instead of class-average achievement. Results based on this alternative source of social comparison information gave a similar pattern of results. In particular, the predictive effect of individual student achievement was positive, whereas the predictive effect of selecting a more able student as the target of comparison (upward comparison in Table 2) was negative. Finally, in Model 3 for agency (Table 2) we evaluated the combined predictive effects of both sources of social comparison information—school-average achievement (generalized other) and upward comparisons (specific other). Although the negative predictive effects of each of these sources of social comparison information were diminished somewhat—compared with models in which each was considered separately—the negative predictive effects of both class-average achievement and upward social comparison were highly significant ( $p < .001$ ) and substantially meaningful. In summary, this first set of models is consistent with a priori predictions in that the BFLPE was replicated for math agency responses based on both class-average achievement (the typical basis of social comparison information based on a generalized other in BFLPE studies) and upward comparison (a typical basis of social comparison informa-

\*  $p < .05$

tion based on comparison with a selected target person in social comparison studies). Furthermore, when both of these sources of social comparison information were considered simultaneously in a single model, each made substantial, unique contributions.

**MTSPP.** A parallel set of models was tested with MTSPP. Consistent with a priori predictions and the nature of the MTSPP task, the predictive effect of class-average achievement was substantially diminished. In fact, the predictive effect of class-average achievement ( $-.05$ ) was not statistically significant ( $p > .05$ ) despite the large sample size (see Model M1 for MTSPP in Table 2). In Model M2 for MTSPP, we tested a parallel model with the second source of social comparison information (upward comparison rather than class-average achievement). Here the predictive effect of upward comparison was significantly negative, although the size of the predictive effect was modestly less than its corresponding predictive effect on math agency ( $-.12$  for MTSPP,  $-.25$  for math agency). Hence, the difference in the negative predictive effects of class-average ability on the two outcome variables ( $-.44$  for agency vs.  $-.05$  for MTSPP) was substantially larger than for MTSPP. Finally, in Model M3 for MTSPP we considered, simultaneously, both sources of social comparison information. In this model, the predictive effect of class-average achievement was again not statistically significant, whereas the statistically significant negative predictive effect of upward comparison was almost identical to that in Model M2 for MTSPP. In summary, this second set of models is also consistent with a priori predictions in that the BFLPE was substantially diminished for MTSPP responses compared with those based on math agency. Whereas the predictive effect of upward comparison MTSPP was diminished, the predictive effect of class-average achievement was not even statistically significant.

**Supplemental analyses.** In supplemental analyses we explored several variations of these models based on both math agency and MTSPP responses. First, we explored the extent of generality of the predictive effects across different classes by allowing the individual student Level 1 variables (individual achievement and upward comparison) to be random in each of the various models. However, because the resulting variance components were not statistically significant (indicating a lack of class-to-class variation in the predictive effects), these supplemental analyses were not considered further. Nevertheless, these results are important, providing an extremely powerful test of and support for the generalizability of the results across the 64 math classes considered in Study 2.

Second, we explored the implications of considering alternative representations of the direction of comparison based on the target comparison classmate. The downward comparison variable (choosing a target person perceived to be less able) did not have statistically significant predictive effects for any of the models when considered in isolation (instead of upward comparison in models shown in Table 2) or when considered in combination with either of the other direction of comparison variables (upward comparison or up-down comparison). Whereas the up-down comparison variable (downward =  $-1$ , equal =  $0$ , upward =  $+1$ ) also had the expected negative predictive effect in each of the relevant models, its predictive effect was smaller than the upward comparison variable presented here. Based on these supplemental results, we present

only results based on the upward comparison that was the primary focus of the present investigation. However, these supplemental results are substantively important, indicating that predictive effects of the direction of comparison apparently are not symmetric. In particular, whereas there are negative predictive effects of upward comparison, there are apparently no positive predictive effects of downward comparison. Although beyond the scope of the present investigation (but see Aspinwall & Taylor, 1993; Diener & Fujita, 1997; Marsh, Tracey, & Craven, 2006), this is a finding that warrants further research.

## Overall Discussion and Implications

### *BFLPE: Importance of Normative and Absolute Frames of Reference*

Our study is apparently the first to provide clear support for the importance of distinguishing between normative and absolute frames of reference in the evaluation of the BFLPE. An overarching concern of both Studies 1 and 2 was how well the BFLPE generalizes to other academic self-belief constructs, particularly those that invoke a normative or social comparison frame of reference and those based on a more absolute frame of reference. The results of the present investigation are consistent with earlier research showing that the internal comparison process (using results in one school subject as a basis for formulating ASCs in another school subject) was evident only in self-concept responses that invoked a social comparison frame of reference but not in self-efficacy responses that invoked an absolute frame of reference. However, this distinction between normative and absolute frames of reference has apparently not been systematically evaluated in relation to the BFLPE, frame-of-reference effects based on comparisons with other students, and the broader field of social comparison research. More generally, the results make a potentially important contribution to better understanding the relevance of frame-of-reference effects to different academic self-belief constructs.

In Study 1 we compared the strength and generalizability of the BFLPE for self-concept with those for other self-belief constructs on the basis of nationally representative samples of 15-year-old students from 26 different countries. Results provided impressive support for the negative effect of school-average ability on ASC and the generalizability of this BFLPE across the different countries. Also consistent with a priori predictions, the BFLPEs were much weaker for each of four other self-belief constructs (generalized self-efficacy, control expectations, control strategies, and effort persistence). There were, however, differences in the size of the effects of school-average achievement in these other four self-belief constructs. Interestingly, the negative effect of school-average achievement was more negative for the construct actually labeled *self-efficacy* than for the other three self-belief constructs. These differences, however, were consistent with a priori predictions based on the nature of the wording of items—the extent to which they implicitly invoke social comparison processes in forming responses to them. This is consistent with our claim that it is the nature of the situational demands and the nature of the items used in self-belief measures that distinguishes this construct from the ASC construct in relation to frame-of-reference effects. Furthermore, this distinction between self-efficacy and self-concept

apparently does not hold—or holds to a lesser extent—for general self-efficacy measures for which the criterion of successful performance is not an explicit part of the item.

Predictions about the diminished role of social comparison information in the BFLPE were based in part on results for test-specific measures of self-efficacy (Marsh et al., 1991). However, measures included in the large cross-national OECD database used in Study 1 were not based on responses in which the response scale was clearly “absolute” as in traditional self-efficacy scales. In order to provide a more direct test of these predictions, Study 2 evaluated the BFLPE for math agency and MTSP. Although agency is sometimes considered to be a central component of self-efficacy, the nature of the items (see Appendix A) clearly invokes the use of comparative information and, at least in this respect, is more similar to typical operationalizations of self-concept than to measures of test-specific self-efficacy. Hence, it is not surprising that the results based on math agency provided clear support for the BFLPE (positive effects of individual achievement and negative effects of class-average achievement). More importantly in relation to our claims about the theoretical importance of the distinction between absolute and normative comparisons, the effect of class-average achievement was not statistically significant for MTSP responses—there was no BFLPE. In line with the results of Study 1, the results of Study 2 provide strong support for our claim that the size of the BFLPE depends on the nature of the specific items used to measure different self-belief constructs. Furthermore, the extent to which items invoke social comparison processes is a potentially important source of variation in the way that researchers construct other psychosocial constructs that has not been given sufficient attention in previous research.

### *Choice of Comparison Targets and the BFLPE*

Our research is apparently the first to demonstrate the simultaneous, independent negative predictive effects of two sources of social comparison information; the negative predictive effect of class- or school-average ability (the BFLPE) widely reported in educational psychology research and negative predictive effects of upward comparison strategies with individual target persons widely studied in SCT studies in social psychology research. In this respect, we bring together two distinct areas of research typically based on very different experimental designs and methodology, showing that each has the potential to contribute to the other.

An important focus of SCT research in social psychology has been the strategies that individuals use to select comparison target persons (e.g., upward and downward comparison strategies) to maximize competing needs. In BFLPE research, this target comparison is assumed to be a generalized other, as operationalized by class- or school-average achievement. Whereas this may be a reasonable assumption within the imposed social comparison paradigm (the basis of BFLPE research), even in this highly constrained environment, individual students have considerable flexibility in choosing individual classmates who might serve as a basis for social comparison. In this respect, the results of Study 2 are important as they demonstrate that both sources of social comparison information (class-average responses and upward comparisons) contribute negatively to self-perceptions of math agency.

It is important to note that each of these sources of social comparison information provides a unique, independent predictive effect that cannot be explained by the other. In this sense, the comparison target classmate selected by a student is more than just a “noisy” reflection of the class average as a basis of comparison (i.e., a “class average” based on a response of one randomly selected student that would obviously have considerable random error compared with the class average based on all students within the class). Had the target comparison classmate merely been a randomly selected student, then the effect of upward comparison in Study 2 would have not made an independent contribution after controlling for the effect of class-average achievement. Although consistent with a priori predictions based on the BFLPE, the results have important implications for both BFLPE and SCT research. Importantly, the uses of generalized and specific others are not mutually exclusive alternatives. Individuals might simultaneously evaluate their performances in relation to both the performances of specific target individuals selected in ways that have been considered in SCT research and in relation to some generalized other performance based on an average performance, as posited in BFLPE research. Hence, there is a need for more research to juxtapose different operationalizations used in SCT and BFLPE research. In particular, BFLPE studies should evaluate microlevel social comparison strategies used by individual students in their selection of target comparison classmates, whereas SCT research should incorporate macrolevel social comparison strategies based on class-average information (or some alternative representation of the “generalized other”) as well as microlevel strategies that have been the focus of this research. In relation to both operationalizations, there seems to be an important role for mixed-methods research in which the largely quantitative approach used in this research is supplemented with qualitative research to more fully explicate these alternative social comparison processes.

### *Limitations and Directions For Further Research*

As with all research studies, it is relevant to note potentially important limitations that may influence our interpretations of the results as well as providing useful directions for future research. Particularly in large-scale studies like those considered here, there is often an emphasis on using brief measures. This is clearly the case with the OECD PISA Student Approaches to Learning instrument (Marsh, Hau, et al., 2006) as the constructs were measured using brief scales, typically items selected from longer scales. This was particularly a concern with the MTSP construct in Study 2 that was based on a single response (a postdiction estimate of the number of test items a student had answered correctly). Although somewhat cumbersome in a survey study, it might be possible for students to estimate the probability that they answered individual items correctly as a basis of providing multiple indicators—a strategy like that used in many self-efficacy measures in educational settings (e.g., Marsh et al., 1991).

Previous BFLPE research, as was the case in the present investigation, has identified the BFLPE in relation to both school- and class-average ability. The theoretical model posits the contextual effects based on group-average achievement so that predictions are similar whether the “group” refers to the school or the class. Because class- and school-average ability are usually highly related (and confounded), it is typically difficult to separate out the

effects of one from the other. However, if there is clearly delineated ability grouping within schools such that there are large, systematic differences in class-average ability within the same school, it is reasonable to expect class-average ability effects in addition to school-average effects. Nevertheless, BFLPE studies have typically been unable to clearly distinguish between the effects of class-level achievement and school-level achievement (see discussion by Trautwein et al., 2006). Because there was no class-level information in Study 1 or school-level information in Study 2, we were not able to pursue this distinction in the present investigation. It is, however, a relevant issue for consideration in further research.

The results of the present investigation suggest that the BFLPEs were reasonably consistent across countries in the large cross-national PISA study (based on the very small country-to-country variation shown in Table 1; see further discussion by Marsh & Hau, 2003). Whereas the sample of countries is diverse, we note that Western countries are overrepresented. This is particularly relevant in that the current round of PISA data (collected in 2006 and released in late 2007) is even more diverse, with a larger number of countries overall and more non-Western countries. Hence, this new database should provide an even stronger basis for evaluating the cross-national generalizability of the BFLPE and country-level variables that might explain any such variation found between countries. We also note that most BFLPE research—like the present investigation—is based on responses by adolescents in high school settings (but see Craven, Marsh, & Print, 2000; Marsh, Chessor, Craven, & Roche, 1995). Particularly in relation to new issues raised here—the distinction between normative and absolute frames of reference and the distinction between individual- and group-average (generalized other) bases of social comparison—it is relevant to explore developmental differences and the role of social comparison in the formation of self-concept by young children.

An important contribution of the present investigation is the distinction between normative and absolute frames of reference and the implications for social comparison processes. Although our results are clearly consistent with this distinction, systematically manipulating the wording of the items and the response language for the same construct would provide a stronger test. Thus, for example, self-efficacy items could be expressed in terms of absolute standards (e.g., probability of getting an item correct, the percentage of test items that will be correctly answered, the amount of time taken to run 100 m), relative standards (how well one will do on a test relative to other students, what place one will get in a 100-m race), or ambiguous frames of reference (doing well on a test, doing well on a 100-m race). In this way it would be possible to unconfound the content of the construct from the nature of the items and the responses used to assess it. This is a particularly relevant consideration in self-efficacy research in which the nature of the self-efficacy construct seems to imply an absolute frame of reference but actual measurement instruments are sometimes based on a normative frame of references.

An important contribution of our research was to demonstrate that upward comparisons based on the target comparison classmate made an independent contribution to the prediction of ASC beyond what could be explained in terms of negative effects of class-average ability (the BFLPE). However, an important direction of future research is to refine this measure of target comparison

classmate and more fully explicate the psychological processes involved. Thus, for example, it might be useful to compare these results with those based on randomly assigned target comparison classmates who are not actually chosen by the student, thereby unconfounding the manner and direction of choice. It would also be useful to use a mixed-methods design that combines the quantitative approach emphasized here with a more qualitative approach to better understand the processes used to make this choice. Furthermore, whilst SCT research sometimes defines direction of comparison in terms of actual performance differences (based on the test completed as part of the study or previous achievement measures), we emphasized perceived differences as being more critical in terms of self-concept formation. Although perceived and actual differences are likely to be highly correlated, a useful direction of future research would be to more fully explore this distinction.

### *Multilevel Modeling Perspective*

BFLPE research has increasingly used a multilevel modeling approach in which it is possible to appropriately consider variables measured at the individual and group level, and to distinguish between effects that occur at different levels. This is a natural corollary of a simultaneous focus on the differential effects of individual achievement and class- or school-average achievement. A multilevel perspective is not so obviously relevant to SCT research that incorporates measures only at the individual level. However, SCT may also involve multilevel data in which individuals are nested within groups that occur naturally (e.g., neighborhoods, schools, institutions) or are constructed by the experimenter as part of the study. Not only is multilevel modeling a more appropriate way to analyze such multilevel data, but it also opens up new research questions not obvious to researchers who ignore the multilevel nature of their data (e.g., the extent to which the results generalize over different groups and group-level variables such as climate that might be related to individual-level variables or account for group-to-group differences in the effects of social comparison information). More generally, a multilevel perspective would facilitate the juxtaposition of individual- and group-level bases of comparison that have been emphasized in SCT and BFLPE research, respectively.

## Appendix A

## Summary of Scales Used in Studies 1 and 2

## Scale

## Study 1

## Control Strategies

1. When I study, I start by figuring out exactly what I need to learn.
2. When I study, I force myself to check to see if I remember what I have learned.
3. When I study, I try to figure out which concepts I still haven't really understood.
4. When I study, I make sure that I remember the most important things.
5. When I study, and I don't understand something I look for additional information to clarify this.

## Effort and Perseverance

6. When studying, I work as hard as possible.
7. When studying, I keep working even if the material is difficult.
8. When studying, I try to do my best to acquire the knowledge and skills taught.
9. When studying, I put forth my best effort.

## Perceived Self-Efficacy

10. I'm certain I can understand the most difficult material presented in texts.
11. I'm confident I can understand the most complex material presented by the teacher.
12. I'm confident I can do an excellent job on assignments and tests.
13. I'm certain I can master the skills being taught.

## Control Expectation

14. When I sit myself down to learn something really difficult, I can learn it.
15. If I decide not to get any bad grades, I can really do it.
16. If I decide not to get any problems wrong, I can really do it.
17. If I want to learn something well, I can.

## Academic Self-Concept

18. I learn things quickly in most school subjects.
19. I'm good at most school subjects.
20. I do well in tests in most school subjects.

## Study 2

## Math Agency

1. When it comes to math, I'm pretty smart.
2. I can learn the things I need for math pretty fast, without really trying a lot.
3. I'm pretty smart in mathematics—even without working very hard.

# Longitudinal Analysis of the Role of Perceived Self-Efficacy for Self-Regulated Learning in Academic Continuance and Achievement

Gian Vittorio Caprara, Roberta Fida,  
Michele Vecchione, Giannetta Del Bove,  
Giovanni Maria Vecchio, and Claudio Barbaranelli  
“Sapienza” University of Rome

Albert Bandura  
Stanford University

The present study examined the developmental course of perceived efficacy for self-regulated learning and its contribution to academic achievement and likelihood of remaining in school in a sample of 412 Italian students (48% males and 52% females ranging in age from 12 to 22 years). Latent growth curve analysis revealed a progressive decline in self-regulatory efficacy from junior to senior high school, with males experiencing the greater reduction. The lower the decline in self-regulatory efficacy, the higher the high school grades and the greater the likelihood of remaining in high school controlling for socioeconomic status. Reciprocal cross-lagged models revealed that high perceived efficacy for self-regulated learning in junior high school contributed to junior high school grades and self-regulatory efficacy in high school, which partially mediated the relation of junior high grades on high school grades and the likelihood of remaining in school. Socioeconomic status contributed to high school grades only mediational through junior high grades and to school drop out both directly and mediational through junior high grades.

**Keywords:** perceived self-regulatory efficacy, self-regulated learning, academic achievement, latent growth curves, school drop out

The present study analyzed the developmental course of perceived self-efficacy for self-regulated learning from junior high to high school and its contribution to academic achievements and the likelihood of remaining in school. The role of perceived self-efficacy in the academic domain has been examined at three different levels. These include students' beliefs in their efficacy to regulate their learning activities and to master academic subjects, teachers' beliefs in their instructional efficacy to manage classrooms and to motivate and promote learning in their students, and faculties' collective sense of efficacy that their schools can accomplish significant academic progress. These different lines of theorizing and research have been reviewed in some detail (Bandura, 1997; Pajares & Urdan, 2006; Schunk & Pajares, 2002).

The present longitudinal study focuses on the central role played by perceived self-regulatory efficacy in one's academic self-development and functioning. The capacity to regulate one's thoughts, motivation, affect, and action through self-reactive in-

fluence constitutes one of the core properties of human agency within the conceptual framework of social cognitive theory (Bandura, 2006b; in press). For linguistic brevity, perceived self-efficacy for self-regulated learning will be referred to as *self-regulatory efficacy*.

Self-regulatory efficacy was selected as a key factor because of its growing primacy in contemporary life. Information technologies are globalizing knowledge and altering educational systems (Bandura, 2002). In the past, students' educational development depended on the quality of the schools in which they were enrolled. Students can now exercise greater personal control over their own learning, independently of time and place, through multimedia instruction on the Internet. In this new era, the construction of knowledge will rely increasingly on electronic inquiry. In research in self-instruction through the Internet, students with high efficacy for self-regulated learning are the ones who make the best use of Internet-based instruction (Debowski, Wood, & Bandura, 2001; Joo, Bong, & Choi, 2000). Moreover, the accelerated pace of social, informational, and technological change is placing a premium on capability for self-directed learning and self-renewal. People now have to educate themselves throughout their lifetime.

Within the agentic framework of social cognitive theory, self-regulation operates through three generic subfunctioning (Bandura, 1986; in press). These include self-monitoring of one's activities and the cognitive and social conditions under which one engages in them; adoption of proximal goals, rooted in a value system, to motivate and guide one's efforts and the strategies for realizing the challenges set for oneself; and the exercise of self-influence that includes the enlistment of self-motivating incentives and social supports to sustain one's academic pursuits. Different

models of self-regulation have been proposed (Schunk & Zimmerman, 1994; Zimmerman & Schunk, 1989). Although the models differ in particulars, they generally include self-assessment through self-monitoring, instrumental cognitive and metacognitive guides, goal setting, and self-motivational strategies.

Analyses of the role of self-regulation in the acquisition of knowledge and cognitive skills have been largely confined to enhancement of academic learning by use of task-related metacognitive strategies. A number of theorists have addressed the pragmatics of self-regulation in terms of selecting appropriate strategies, testing one's comprehension and state of knowledge, correcting one's deficiencies, and recognizing the utility of cognitive strategies (Brown, 1987; Paris & Newman, 1990). Self-directive use of cognitive strategies is a part of the way in which students regulate their own cognitive development and functioning. Social cognitive theory integrates the cognitive and metacognitive factors with motivational self-regulation mechanisms (Bandura, 1986; Zimmerman, 2000; Zimmerman & Cleary, 2006). This theory expands the conception of self-regulation in two directions. First, it incorporates a larger set of self-regulatory mechanisms governing cognitive functioning. Second, it encompasses social and motivational skills as well as cognitive ones.

Zimmerman (1989, 2000) has been the leading exponent of an expanded model of academic self-regulation. Viewed within the conceptual framework of social cognitive theory, people must develop skills to regulate the motivational, affective, and social determinants of their intellectual functioning as well as the cognitive aspects. This requires bringing self-influence to bear on every aspect of their learning experiences. There is a major difference between possessing self-regulatory knowledge and skills and being able to put them into practice and to stick with them. Self-regulatory skills will not contribute much if students cannot get themselves to apply them persistently in the face of difficulties, stressors, and competing attractions. Firm belief in one's self-regulatory efficacy provides the staying power. Children's belief that they can regulate their own learning raises their efficacy for academic activities. Their academic efficacy increases their achievement both directly and by raising their academic aspirations (Zimmerman & Bandura, 1994; Zimmerman, Bandura, & Martinez-Pons, 1992).

The belief that people hold about their capabilities affects the quality of their functioning through four major processes: cognitive, motivational, affective, and decisional (Bandura, 1997). The independent contribution of efficacy beliefs to cognitive functioning is verified experimentally by Bouffard-Bouchard (1990) in research in which high or low self-efficacy beliefs were instilled arbitrarily in students irrespective of their actual performance. Students whose sense of efficacy was raised set higher aspirations for themselves, showed greater strategic flexibility in the search for solutions, achieved higher intellectual performances, and were more accurate in evaluating the quality of their performances than were students of equal cognitive ability who were led to believe they lacked such capabilities. Efficacy beliefs contributed to accomplishments both motivationally and through support of strategic thinking. Self-regulatory efficacy also raises academic goals and aspirations, personal standards for the quality of work considered to be acceptable, and beliefs in one's capabilities for academic achievement after one controls for instructional level, prior aca-

demical performance, and relevant aptitude (Zimmerman & Bandura, 1994; Zimmerman et al., 1992).

The present study focused on adolescence because it is an especially taxing transitional phase that presents a host of new challenges (Bandura, 2006a; Graber, Brooks-Gunn, & Petersen, 1996; Pajares & Urdan, 2006). Adolescents have to manage major biological, educational, and social role transitions concurrently. Learning how to deal with pubertal changes, differently structured school environments, enlarged peer networks, and emotionally invested partnerships becomes important. Moreover, this is the time when the roles of adulthood must begin to be addressed in almost every dimension of life. Adolescents must also begin to consider seriously what they want to do with their lives (Bandura, Barbaranelli, Caprara, & Pastorelli, 2001). They have to master many new skills and the ways of adult society. The way in which adolescents develop and exercise their personal efficacy during this period can play a key role in setting the course their life paths take (Bandura, 2006b; Pajares & Urdan, 2006).

The transition from middle-level school to high school involves a major environmental change that can tax personal efficacy (Wigfield, Eccles, Schiefele, Roeser, & Davis-Kean, 2006). Under the new social structural arrangements, the adolescents have to reestablish their sense of efficacy, social connectedness, and status within an enlarged heterogeneous network of new peers. During this adaptational period, young adolescents sense some loss of personal control, become less confident in themselves, and suffer some decline in self-motivation (Eccles & Midgley, 1989). But these adverse effects are neither universal nor enduring for every adolescent. It was predicted that adolescents who have a high sense of efficacy to regulate their learning activities in junior high school are likely to do better academically in high school and less likely to drop out of school.

We used a latent growth curve approach (Duncan & Duncan, 1995; McArdle, 1988; McArdle & Anderson, 1989; Meredith & Tisak, 1990; Stoolmiller, 1994) to investigate the level and stability of self-regulatory efficacy and the extent to which these beliefs at age 12 and their subsequent change can predict academic achievement at the end of high school in males and females.

For reasons given earlier, we predicted decline in self-regulatory efficacy after the transition from junior school to high school. In a cross-national study on a sample of 1,180 children ranging in age from 10 to 15 years (Pastorelli et al., 2001), girls exhibited a higher sense of efficacy to exercise control over their academic development than did boys. It was, therefore, expected that females would be more successful than males in maintaining their perceived efficacy to manage their academic activities as they progress in the educational system.

We used reciprocal cross-lagged relationships to evaluate the unique contribution of self-regulatory efficacy in junior high school to academic achievement in junior and senior high school and to continuing in school over and above the effects of prior academic performance and socioeconomic status (SES). Both experimental and naturalistic studies have shown that perceived academic self-efficacy makes an independent contribution after the effects of prior performance are partialled out (Bandura, 1997; Bouffard-Bouchard, 1990; Gore, 2006; Zimmerman & Martinez-Pons, 1986).

It was predicted that self-regulatory efficacy in junior high would contribute to academic achievement and continuance in

school through two pathways: by supporting a high sense of self-regulatory efficacy in high school and by mediating the effects of junior high academic performance and SES.

SES was selected because it can affect academic aspirations, availability of resources conducive to intellectual development, choice of peers who may support academic pursuits or disengagement from them, and the range of occupational pursuits that are seriously considered (Bandura, Barbaranelli, Caprara, & Pastorelli, 1996; Bandura et al., 2001; Sirin, 2005). Diverse lines of evidence show that SES affects performance, in large part, through its impact on psychosocial processes rather than directly (Bandura et al., 1996, 2001; Elder, 1995; Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999). It was, therefore, predicted that SES influences academic achievement in high school and school drop out both directly and indirectly, through its impact on self-regulatory efficacy and academic performance in junior high school.

## Method

### Participants

The participants were part of an ongoing longitudinal project that began in 1989 designed to clarify the personal and social determinants of developmental pathways from childhood to early adulthood. A total of 412 children (196 males and 216 females) participated in the study. This longitudinal project used a staggered, multiple cohort design ranging from 1994 to 2004. The study includes two cohorts assessed at six different time points. Both cohorts were age 12 years at Time (T) 1, age 13 at T2, age 14 at T3, age 16 at T4, age 18 at T5, and age 20 and 22 at T6. Cohort effects were tested and found to be nonsignificant on all variables examined in this study. Therefore, the data from the two cohorts were combined.

Participants were originally drawn from the two public junior high schools in a community located near Rome. This sample represents a socioeconomic microcosm of the larger Italian society, composed of families of skilled workers, farmers, professionals, local merchants, and their service staff. In particular, 16% of families were in professional or managerial ranks, 37% were merchants or employees in various types of businesses, 14% were skilled workers, 31% were unskilled workers, 1% were retired, and 1% were unemployed. This occupational socioeconomic distribution matches the national profile (Istituto Italiano di Statistica, 2002). The composition of the family also matches national data with regard to type of families and number of children. Most children were from intact families (94%). The participation rate was high during the longitudinal data collection: 100% from T1 to T2 for both cohorts; 97% and 96% from T1 to T3 for first cohort and second cohort, respectively; 90% and 96% from T1 to T4 for first cohort and second cohort, respectively; 81% and 93% from T1 to T5 for first cohort and second cohort, respectively; 62% and 69% from T1 to T6 for first cohort and second cohort, respectively. Multivariate analysis of variance and Box's M test, carried out separately for males and females, revealed that there were no statistically significant differences on the means of the variables of interest (males:  $F[1, 143] = 1.34$ ,  $\Lambda = .95$ ,  $ns$ ; females:  $F[1, 165] = 1.69$ ,  $\Lambda = .95$ ,  $ns$ ) and on the covariance matrices (males:  $M = 32.24$ ,  $F[21, 38033.7] = 1.46$ ,  $ns$ ; females:  $M = 21.06$ ,  $F[21, 12531.5] = 0.93$ ,  $ns$ ) between the participants who provided com-

plete data for the present study and the ones who dropped out over the years.

### Procedures

At T1, T2, and T3 two experimenters administered in the classroom the scale measuring perceived efficacy for self-regulated learning. A stringent consent procedure for the research was followed including, at various stages, parents' consent and approval from school councils and freedom of children to decline participation if they choose to do so. The researchers explained that responses to the questionnaires would be confidential. At T4, T5, and T6 the participants received the questionnaire after being contacted by phone. Adolescents received a small payment (€25 or a dinner token) for their participation.

### Measures

*Perceived efficacy for self-regulated learning.* We assessed perceived efficacy for self-regulated learning (Bandura, 1990) from T1 to T5. This scale was previously validated on Italian samples (Bandura et al., 1996; Caprara, 2001) and American samples (Zimmerman et al., 1992). It includes 11 items that measure children's self-efficacy to plan and organize their academic activities (e.g., "How well can you organize your school work?"), to structure environments conducive to learning (e.g., "How well can you arrange a place to study without distractions?"), and to motivate themselves to do their school work (e.g., "How well can you study when there are other interesting things to do?"). For each item, participants rated the strength of their efficacy to execute the designed activities using a 5-point scale ranging from 1 (*cannot do at all*) to 5 (*highly certain can do*).

A principal-axis factor analysis revealed a one-factor structure at all time points. The percentage of the variance explained ranged from 33% to 38%. Cronbach's alpha was .83 at T1, .85 at T2, .86 at T3, .84 at T4, and .87 at T5.

*Academic achievement.* At the end of junior high school (T3), we assessed children's academic achievement for different subject matters (mathematics, science, language, and social studies) using a five-level grade system. We created a composite measure of academic achievement from the grades assigned by the group of teachers. In T6, high school academic achievement was assessed with a stringent examination system. The final high school grade was based on a national written exam supplemented with an oral exam. Students reported whether they graduated from high school and, if so, their final grade. In the Italian educational system, grades range from 60 to 100. Final high school grades and high school drop out (0 = drop out; 1 = graduated) served as the outcome variables.

As a check on students' reports of their high school grades, we compared the self-reported grades for a sample of 30 students against the grades recorded by the schools. In 29 of the 30 students, the self-reported grade was identical with the recorded school grades.

*SES.* Family SES was based on the occupation and education of the fathers and the mothers (see Sirin, 2005). We performed a confirmatory factor model, using the WLSMV as the method of

Table 1  
Means and Standard Deviations in Self-Regulatory Efficacy, Junior High School, and High School Grades

Self-regulatory efficacy	Males			Females		
	<i>n</i>	<i>M</i>	<i>SD</i>	<i>n</i>	<i>M</i>	<i>SD</i>
T1 (12 years old)	193	3.07	0.48	213	3.21	0.43
T2 (13 years old)	196	3.05	0.44	216	3.20	0.45
T3 (14 years old)	188	3.05	0.44	209	3.18	0.44
T4 (16 years old)	181	2.89	0.47	202	3.07	0.48
T5 (18 years old)	170	2.88	0.51	190	3.12	0.46
Junior high school grades (T4)	191	2.95	0.84	210	3.16	0.86
High school grades (T6)	77	75.34	13.07	132	80.13	12.63

Note. The items of the perceived efficacy for self-regulated learning scale were on a 5-point scale ranging from 1 (*cannot do at all*) to 5 (*highly certain can do*). Junior high school grades ranged from 1 to 5. High school grades ranged from 60 to 100.

estimation<sup>1</sup> (Muthén & Muthén, 1998), where SES was defined by parent’s education and occupation. After establishing the monodimensionality of this set of indicators (52% of variance explained;  $\alpha = .77$ ), we estimated the factor score of SES. This variable was included as observed time invariant covariate in the analysis.

Results

Descriptive Statistics

Observed means and standard deviations for self-regulatory efficacy across the five time points (from T1 to T5) are reported in Table 1 separately for males and females.

In longitudinal research it is common to have attrition over time (Hansen, Tobler, & Graham, 1990). With missing data, parameters’ estimation must be adjusted. Among the different methods used for taking into account missing data, we selected the most commonly used maximum-likelihood parameters’ estimation (Muthén & Shedden, 1999; Schafer & Graham, 2002). Thirty-three percent of males and 15% of females dropped out of the school.

Pairwise correlations (disattenuated for unreliability) between self-regulatory efficacy from T1 to T5 are provided in Table 2. They reveal a medium-to-high relative stability across time with lower relations the longer the elapsed time period.

Growth Models

The analysis of self-regulatory efficacy development was conducted within a latent variable framework. We specified a multi-group growth curve model that simultaneously estimated the same pattern of relationships among variables for males and females. To examine gender differences in the estimated parameters, we constrained all parameters to be equal across groups, and we used the chi-square difference test to compare nested models. Modification indices were used to assess the tenability of the equality constraint imposed across gender.

Two latent variables were specified from multiple indicators, that is, the five repeated measures of self-regulatory efficacy (from T1 to T5). The first factor is the intercept and it represents the baseline of self-regulatory efficacy (T1). The second factor is the slope or the shape of the trajectory over time and its mean gives the growth rate of self-regulatory efficacy.

The following equation shows the mathematical representation of the growth model:

$$y_t = \eta_0 + \eta_1 x_t + \varepsilon_t; \quad t = 1, 2, 3, 4, 5;$$

where  $y_t$  is the observed score at time  $t$ ,  $\eta_0$  is the unobserved score for the intercept factor,  $\eta_1$  is the unobserved score for the growth rate factor, and  $x_t$  is the factor loading relating  $y_t$  to latent growth variables.

Because factor loadings of the slope give the shape of the growth, alternative models were tested and compared with each other. We could establish the parameterization that provided the best fit to the data. We fixed the starting point for self-regulatory efficacy at T1 at 0 for all the models. Following McArdle and Anderson (1989), the first model tested was a no-growth model (with values for males followed by values for females),  $\chi^2(29, N = 196; 216) = 110.70, p < .001$ , comparative fit index (CFI) = .88, root-mean-square error of approximation (RMSEA) = .117 (.094; .140), standardized root-mean-square residual (SRMR) = .170. This model assumes that the level of self-regulatory efficacy is stable over time except for a random error component at each point of assessment. The second is a linear model representing a constant change over time,  $\chi^2(23, N = 196; 216) = 26.28, p = .29$ , CFI = 1.00, RMSEA = .026 (.000; .065), SRMR = .090. In this model we fixed the factor loadings at 0, 0.5, 1, 2, and 3. The third model examines a nonlinear growth where the form of the change over time is not specified a priori,  $\chi^2(20, N = 196; 216) = 19.70, p = .48$ , CFI = 1.00, RMSEA = .000 (.000; .059), SRMR = .083. Several parameters were added to the examined models. In particular, we specified the covariance between the residual variance of self-regulatory efficacy. Because these models are nested, we performed a chi-square differences test ( $\Delta\chi^2$ ) to compare the models (Bollen, 1989). This test revealed that the linear model provided the best fit to the data compared to the no-growth model,  $\Delta\chi^2(6) = 84.42, p < .001$ . The chi-square for the linear model was not statistically different from the chi-square for the nonlinear model,  $\Delta\chi^2(3) = 6.58, p = .086$ , but it was more parsimonious. Table 3 presents parameter estimates for the linear model.

The mean of the slope reveals a decline in self-regulatory efficacy over the time course for male and female subsamples.

<sup>1</sup> The WLSMV is a weighted least square parameter estimates that uses a diagonal weight matrix with robust standard errors and mean and variance adjusted chi-square test statistics (see Muthén & Muthén, 1998). This estimator is particularly suited for dealing with nonnormal or categorical data (Flora & Curran, 2004).

Table 2  
Correlations Among Self-Regulatory Efficacy Across Time

Variable	1	2	3	4	5
1. T1 (12 years old)	—	.71**	.70**	.57**	.52**
2. T2 (13 years old)	.67**	—	.76**	.64**	.59**
3. T3 (14 years old)	.63**	.59**	—	.68**	.68**
4. T4 (16 years old)	.50**	.47**	.60**	—	.81**
5. T5 (18 years old)	.27*	.43**	.50**	.58**	—

Note. Coefficients for females are above the diagonal; coefficients for males are below the diagonal. Correlations were disattenuated for unreliability.  
\*  $p < .05$ . \*\*  $p < .01$ .

However, the decrease was greater for males, as confirmed by a significant chi-square difference among constrained and unconstrained models,  $\Delta\chi^2(1) = 12.19$ ,  $p < .001$ . In particular self-regulatory efficacy decreases .077 for males and .035 for females each year. Moreover, the level of self-regulatory efficacy at baseline was higher for females,  $\Delta\chi^2(1) = 4.498$ ,  $p < .05$ . The variances of the growth factors were also estimated, and they indicated that there was a significant variation in individual differences both in the initial status and in the growth rate for males as well as for females. Figure 1 shows the trajectory for self-regulatory efficacy across junior high school and high school levels in the educational system for both males and females.

### Predicting High School Grades and School Drop Out

After establishing the best fitting growth curve model, we added SES as the time invariant covariate. To evaluate the contribution of the initial level of self-regulatory efficacy and its change over time on academic achievement, we tested two models. In the first model, we considered high school grades as the outcome. In the second model the probability of graduating from high school served as the second outcome.

The results of the first model are provided in Table 4. The posited model provided a good fit to the empirical data,  $\chi^2(41, N = 196; 216) = 52.90$ ,  $p = .10$ , CFI = .98, RMSEA = .038 (.000, .064), SRMR = .095. The higher the self-regulatory efficacy at T1, the higher the grades at the end of the high school. Moreover, the less self-regulatory efficacy declined from T1 to T5, the higher the

high school grades. The higher the SES the smaller the decline of self-regulatory efficacy. SES did not influence self-regulatory efficacy at T1. Although SES did not directly influence the grades, it contributed indirectly through its influence on self-regulatory efficacy change (total indirect effects were  $\beta = .11$ ,  $t = 3.93$  for males and  $\beta = .12$ ,  $t = 3.93$  for females). There were no significant differences on any of the parameters estimated in the samples of males and females. The model explains 17% of variance in high school grades for males and 21% of variance for females.

The results of the second model concerned with school drop out are provided in Table 5. The posited model also provided a good fit to the data,  $\chi^2(21, N = 107, 142) = 20.65$ ,  $p = .48$ , CFI = 1.00, RMSEA = .000; weighted root-mean-square residual = .89. The higher self-regulatory efficacy at T1, the lower the probability of dropping out of high school. Moreover, the more self-regulatory efficacy decline from T1 to T5, the higher the probability of dropping out of school. Furthermore, the higher the SES, the lower the probability of dropping out and the lower the decrease in self-regulatory efficacy. As in the case of grades, SES did not influence self-regulatory efficacy measured at T1. There were no significant differences on any the parameters estimated in the samples of males and females. The model explained 55% of variance of dropping out for males and 57% of variance for females.

### The Relation of Perceived Efficacy for Self-Regulated Learning to High School Grades and School Drop Out

We performed multigroup structural equation modeling to examine the role of self-regulatory efficacy, prior academic performance, and SES on high school grades and high school drop out. Except for a small variation in the role of SES in the two outcomes, the pattern of relations among the variables in the structural model are highly similar for high school grades and high school drop out. The structural relations among the variables are presented in Figures 2 and 3.

As shown in the figures, self-regulatory efficacy was relatively stable at the junior high level. Self-regulatory efficacy in junior high school contributed to both junior high grades and self-regulatory efficacy in high school. Self-regulatory efficacy in high school partially mediated the relation of junior high grades to high school grades (total indirect effects were  $\beta = .07$ ,  $t = 3.19$  for males and  $\beta = .07$ ,  $t = 3.19$  for females) and school drop out (total indirect effects were  $\beta = .06$ ,  $t = 2.13$  for males and  $\beta = .06$ ,  $t = 2.13$  for females). Self-regulatory efficacy thus contributed

Table 3  
Growth Curve Parameters for the Linear Model

Growth parameter	Males		Females	
	Parameter	<i>t</i>	Parameter	<i>t</i>
Mean				
Intercept	3.09	105.24	3.20	117.88
Slope	-.08	-5.56	-.03	-3.23
Variances				
Intercept	.11	5.98	.12	7.31
Slope	.01	3.59	.01	4.32
Correlation				
Intercept ↔ Slope	-.38	-2.23	-.26	-2.09

Note. The *t* values greater than 1.96 (1.65 for variances) indicate a parameter estimate that is significantly different from zero. Parameters estimated for correlations (↔) are presented in standardized form. All other parameter estimates are presented as unstandardized coefficients.

Figure 1. Differential change in self-regulatory efficacy in male and female students across different levels of education.

uniquely to high school grades and retention in school after we controlled for prior academic achievement.

Junior high grades were also related to high school grades and school drop out and completely mediated the relation of SES to high school grades (total indirect effects were  $\beta = .09$ ,  $t = 2.64$  for males and  $\beta = .10$ ,  $t = 2.64$  for females). In the case of school drop out, SES also contributed directly as well as through its relations to high school grades (total indirect effects were  $\beta = .13$ ,  $t = 4.13$  for males and  $\beta = .14$ ,  $t = 4.13$  for females).

The posited models provided a good fit to the empirical data. Regarding high school grades, the values for the various fit indices were  $\chi^2(17) = 14.85$ ,  $p = .61$ , CFI = 1.00, RMSEA = .000 (.000, .055), SRMR = .065. The model accounted for 25% of the variance in high school grades for males and 28% of the variance for females. The chi-square difference test revealed that all parameters were equal across gender, with the exception of the regression coefficient between self-regulatory efficacy during junior high school. This coefficient was larger for females indicating a slightly higher stability for females.

The model also provided a good fit to the empirical data for high school drop out,  $\chi^2(14) = 9.733$ ,  $p = .78$ , CFI = 1.00, RMSEA = .000, weighted root-mean-square residual = .720. The model

accounted for 53% of the variance of high school performance for males and 61% of the variance for females. The chi-square difference tests suggested that all parameters were equal across gender.

Discussion

Analysis of the trajectory of self-regulatory efficacy reveals a progressive decline as students advance through the educational system. Other studies have reported a similar decline but for students' beliefs in their efficacy for academic achievement, rather than self-regulatory efficacy (Britner & Pajares, 2006; Harter, 1996; Midgley, Feldlaufer, & Eccles, 1989). Several factors may account for students' loss of confidence in their capabilities to manage their academic activities. With increasing levels of schooling, the complexities of academic demands increase and cumulating scholastic deficits become increasingly salient. These changes confront students with adaptational pressures that inevitably shake their sense of efficacy. Students also gain new information about the nature of the academic activities, which provides them with a basis for reappraising their efficacy to get themselves to do them.

Table 4  
Predicting High School Grades: Structural Model

Regression	Males		Females	
	Parameter	t	Parameter	t
Intercept → Grades	.33	4.81	.37	4.81
Slope → Grades	.32	3.20	.34	3.20
SES → Intercept	.09	1.20	.09	1.20
SES → Slope	.18	2.20	.20	2.20
SES → Grades	.08	1.21	.09	1.21

Note. The  $t$  values greater than  $|1.96|$  indicate a parameter estimate that is significantly different from zero. Parameters estimated for regressions (→) are presented in standardized form. SES = socioeconomic status.

Table 5  
Predicting the Probability of Dropping Out of High School: Structural Model

Regression	Males		Females	
	Parameter	t	Parameter	t
Intercept → Drop out	.29	3.72	.30	3.72
Slope → Drop out	.46	2.94	.41	2.94
SES → Intercept	.06	0.76	.06	0.76

SES → Drop out	.46	4.64	.49	4.64

Note. The  $t$  values greater than  $|1.96|$  indicate a parameter estimate that is significantly different from zero. Parameters estimated for regressions (→) are presented in standardized form. SES = socioeconomic status.

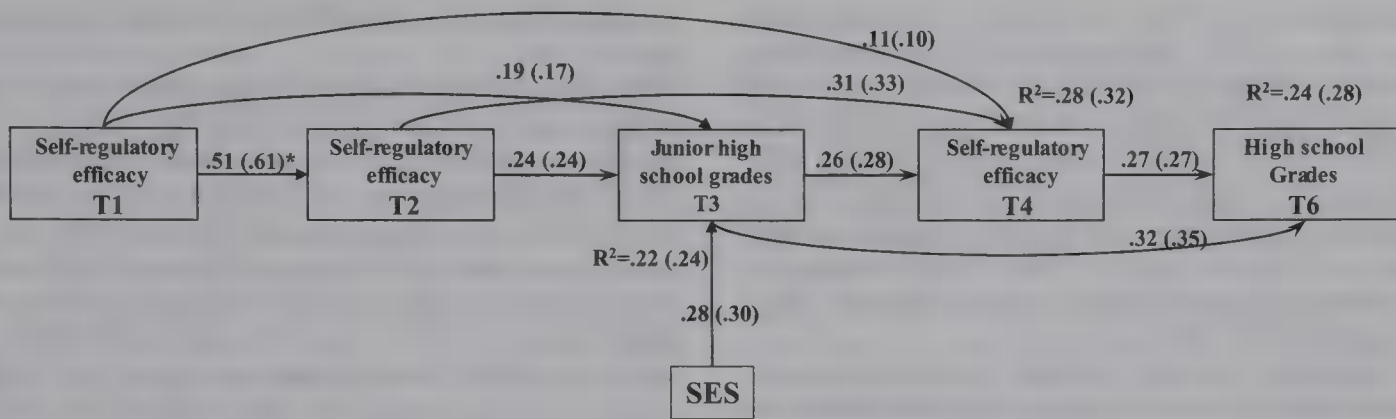

Figure 2. Contribution of self-regulatory efficacy to high school grades operating in conjunction with prior academic achievement and socioeconomic status (SES). The figure includes all of the coefficients that are significant beyond the  $p = .05$  level. The first coefficient in each structural link is for males, and the second coefficient in parentheses is for females.

Academic development is a product of a collaborative process within a social system rather than residing solely in students. Teachers also report a decline across grade level in their efficacy to motivate and promote their students' academic attainments (Bandura, 1997). Thus, students' adaptational problems are likely to be exacerbated if the teachers doubt they can achieve much success by their instructional efforts at higher grade levels (Midgley et al., 1989). Moreover, as students progress to late adolescence and young adulthood there are more competing activities that command their attention. Students report the lowest sense of efficacy to manage their academic activities when there are other interesting things to do (Zimmerman et al., 1992).

Both the initial level of self-regulatory efficacy and the degree of decline vary as a function of gender. Compared to male students, female students exhibit higher self-regulatory efficacy and a lesser decline as they progress in the educational system. The differential gender level is replicated cross-culturally. Female students in both Eastern and Western European countries exhibit higher perceived efficacy to regulate their academic activities than do male students (Pastorelli et al., 2001). The findings of the present study reveal that this gender gap widens as students progress in the educational system. Pastorelli and her collaborators

(2001) also found that students in more authoritarian systems perceive themselves as less efficacious for self-directed learning.

There are several possible explanations for the gender gap in self-regulatory efficacy. During the socialization process, girls are generally subjected to more social constraints on the range of activities they can engage in, especially outside the home, than are boys (Bussey & Bandura, 1999). Attractive competing options reduce opportunities to develop a sense of efficacy for self-directed academic learning and put a strain on efforts to stick to academic tasks. Differences in social and normative influences may also undermine the differential development and exercise of self-regulatory efficacy in the academic domain. Peer pressures for engagement in activities that compete with academic pursuits are likely to be stronger for boys than for girls (Jessor, Donovan, & Costa, 1991; Ogbu, 1990). Research is also needed to determine whether the educational system instills a belief of lesser academic self-regulatory efficacy in males, as suggested in research by Dweck and her collaborators (Dweck, Davidson, Nelson, & Enna, 1978).

The developmental trajectory is an aggregate measure for the students as a whole. It varies not only by gender but as a function of belief in one's efficacy to exercise some control over one's

Figure 3. The role of self-regulatory efficacy in school drop-out operating in conjunction with prior academic achievement and socioeconomic status (SES). The figure includes all of the coefficients that are significant beyond the  $p = .05$  level. The first coefficient on each structural link is for males, and the second coefficient in parentheses is for females.

educational development. Thus, a high level of self-regulatory efficacy in junior high is accompanied by a lesser decline in perceived efficacy to manage learning activities with age, higher academic achievement in high school, and a lower likelihood of dropping out of school. These findings are in accord with those from other spheres of life showing that strong belief in one's personal efficacy enables people to weather taxing and stressful conditions and facilitates recovery from adverse experiences (Allen, Leadbeater, & Aber, 1990; Benight & Bandura, 2004; Lent, Brown, & Larkin, 1984).

In the longitudinal analysis, students' perceived efficacy to regulate their learning activities at the junior high level contributed to their academic achievement in high school and their likelihood of completing their high school education. Self-regulated efficacy retained its relation to academic achievement and continuance in school after we controlled for variations in prior academic performance and socioeconomic level. Academic competence is not a fixed property that one has in one's behavioral repertoire (Bandura, 1990; Sternberg & Kolligan, 1990). Rather, it is the product of ability factors and a host of self-regulatory and motivational influences (Bandura, 1997). Hence, control for prior performance not only controls for the effects of actual self-regulatory efforts but for other possible influences as well.

Findings from diverse lines of research on the contributions of self-efficacy beliefs to academic achievement further confirm that belief in one's capabilities contributes independently to academic achievement rather than simply being an ephiphenomenal reflection of prior performance (Bandura, 1997; Pajares & Schunk, 2001; Schunk & Zimmerman, 1994). The unique contribution applies equally for perceived efficacy to regulate one's learning activities (Zimmerman & Bandura, 1994; Zimmerman et al., 1992).

Advancing knowledge on academic self-development requires converging evidence from diverse methodologies because no one approach can do it alone. The research cited above sheds light on the influential role of perceived self-regulatory learning based on experimental and short-run prospective studies. The present analysis extends the analysis longitudinally. Mulaik (1987, 1993, 2001) advanced a probabilistic conception of causality that is applicable both to experimental and naturalistic studies. In his conception, causality is expressed as functional relation between variables with total independence providing the necessary condition for probabilistic causality (Mulaik, 1993). The posited conceptual model specifies the relations among the variables by fixing and constraining certain parameters in the model (Mulaik, 2007). Goodness-of-fit indices provide the means for evaluating the posited structural model. Although no single method can prove causation, verifying functional relations among factors in longitudinal analysis increase confidence in theoretically specified paths of influence.

Nor is perceived self-regulatory efficacy simply a reflection of SES. Although influenced by one's socioeconomic life conditions, perceived self-regulatory efficacy contributes independently to academic attainments and completion of high school education. These findings are in accord with those of other studies showing that the impact of SES on psychosocial functioning is, in large part, mediated through its effects on people's beliefs on their efficacy to manage their life conditions (Bandura et al., 1996, 2001; Elder, 1995; Elder, Conger, Foster, & Ardeit, 1992;

Fernández-Ballesteros, Díez-Nicolás, Caprara, Barbaranelli, & Bandura, 2002).

SES affected academic performance in high school only indirectly through its impact on prior academic attainment in junior high. However, it affected whether students continued their high school education both directly as well as mediationaly. The link between SES and academic outcomes is indirect because differences in capital can lead to variations in learning opportunities. For example, family SES may provide supportive relationships among parent and school collaborations (Coleman, 1988; Dika & Singh, 2002; Sirin, 2005). It may also create quality of educational facilities, instructional materials, teacher experience, and teacher-student ratio (Wenglinsky, 1998) that can affect success in school. Finally, lacking socioeconomic resources and performing marginally in school would create disincentives for remaining in the educational system when one is free to drop out and enter the workforce.

The findings of the present longitudinal study further demonstrate that self-regulatory efficacy can affect the course of life paths through choice processes. Occupationally relevant choices play a key role in setting the course of lifestyle trajectories (Bandura et al., 2001; Lent, Brown, & Hackett, 1994). Dropping out of school can have a widespread effect on one's future life. Many of the participants in this study have gone on to college, others have enrolled in various professional schools, and still others have entered the general workforce without further education. Some have begun to establish families. Additional assessments at the transitional phase into young adulthood should shed further light on how early self-regulatory efficacy sets in motion concatenating psychosocial changes that can eventuate in major long-term impact on one's life conditions.

Prevention of erosion of children's beliefs in their academic capabilities has greater societal implications in contemporary society than it did in the past. Decline in self-regulatory efficacy foreshadows low academic performance and school drop out. Such outcomes foreclose many options in life. In the past, youth with limited schooling had recourse to well-paying industrial and manufacturing jobs demanding minimal cognitive skills. The rapid pace of informational and technological change requires the development of cognitive competencies (Bandura, 2002). Moreover, with rapid change, knowledge and technical skills are quickly outmoded unless they are updated to fit the new occupational demands. Individuals now have to take charge of their self-development over the course of their work life.

The body of knowledge on self-regulatory processes provides guidelines for enhancing students' efficacy to manage their educational development. Some progress has been made in translating this knowledge into operational models that foster self-directedness in academic pursuits (Bandura, 1997; Pajares & Urdan, 2006; Schunk & Zimmerman, 1994; Zimmerman, 1990; Zimmerman & Cleary, 2006). Teachers and parents can teach students how to set goals, monitor their learning progress, and assess their self-efficacy for learning and self-regulation for guiding the level of motivation in ways that build their sense of efficacy for managing their academic activities. Pajares and Urdan (2006) underscored the importance to set short-term goals, foster mastery goal orientation, provide students with frequent and immediate feedback on their academic activities, assess their self efficacy for

adjusting instructional practices, and make self-regulatory practices habitual and automatic.

There are no adaptive benefits to being immobilized by self-doubts about one's capabilities and belief in the futility of effort. Cross-cultural tests of self-efficacy theory demonstrate that a resilient sense of efficacy has functional value regardless of whether one resides in an individualistic or collectivistic cultural system (Bandura, 2002; Bong, 2001; Joo et al., 2000; Lent, Brown, Nota, & Soresi, 2003). The findings of the present study, based on the Italian educational system, lend further support to the cultural generalizability of self-regulatory efficacy as well. It has the same functional value as in other educational systems.

Nick J. Broers  
Maastricht University

School transitions and educational innovations confront students with changes in their learning environment. Though expectations are known to influence perceptions and motivation, which, in turn, influence the effectiveness of any situation, students' expectations for a new learning environment have received little attention. This longitudinal survey, conducted with 1,335 high school students (average age, 15 years), studied students' expectations and subsequent perceptions of 5 characteristics of a new environment (fascinating content, productive learning, student autonomy, interaction, and clarity of goals) and the students' (prospective) dissatisfaction. Results showed that expectations were positively related to later perceptions. Also, high prospective dissatisfaction was related to higher actual dissatisfaction with the environment later on. Investigating expectations and prospective dissatisfaction in relation to student characteristics (i.e., motivational orientations; conceptions of learning; strategies for regulation, information processing, and affective processing) show that motivational problems and fear of failure were risk factors for educational innovations. Furthermore, students' disappointment with the new environment was related to undesirable changes in student characteristics, such as increased fear of failure. The findings stress the importance of preparing students for curricular changes.

*Keywords:* student expectations, student perceptions, educational innovation, disappointment

Students' learning environments change several times during their school career: After kindergarten, they enter primary school, followed by secondary school and, possibly, higher professional education or university. Besides this school change, students are often confronted with educational innovations in school curricula, which cause changes in school practices. Before entering a learning environment, students form expectations and build ideas about how it will be, and these expectations are known to influence subsequent perceptions (e.g., Olson, Roese, & Zanna, 1996). This is highly relevant for education, because it has been shown that students' perceptions of a learning environment are of central importance for its effects on learning (Entwistle, 1991; Entwistle & Tait, 1990). However, the role of expectations in this context has received little attention, and that is a serious omission. Students' development and their pleasure in school are likely to be disturbed when their expectations of a learning environment do not match with their later perceptions.

The current study focused on students' expectations of a new learning environment and the longitudinal effects on their subse-

quent perceptions of this environment. Students' satisfaction or dissatisfaction with the expected and perceived environment was also examined. Additionally, relations between students' expectations and prospective dissatisfaction and their learning-related characteristics were explored, as well as relations between the degree of the mismatch of expectations and later perceptions, and the development of these student characteristics.

The literature on expectations in educational contexts is broad and concerns many aspects, which, however, do not specifically deal with the expectations of a learning environment. Examples include teachers' expectations of student performances (Weinstein, 1998); students' expectations of their own performances (i.e., self-efficacy, Bandura, 1977; Lopez, Lent, Brown, & Gore, 1997); students' expectations about connections between effort and performance in relation to a positive or negative mood state (Erez & Isen, 2002); students' expectations of success in relation to task-avoidance behavior, low achievement, and dissatisfaction (Nurmi, Aunola, Salmela-Aro, & Lindroos, 2003); and students' expectations of the utility of what they are learning for their future in relation to their learning motivation (future-time perspective theory; Kauffman & Hasman, 2004). In each of these studies, clear relationships have been found between expectations and the other variables being studied.

Thus, very little research has been conducted on students' expectations with regard to characteristics of a forthcoming course or learning environment. Twenty years ago, Rosinski and Hill (1986) pointed out the importance of investigating students' expectations of the content of a course and the degree to which the course met these expectations because expectations determine the way in which students enter a course or learning environment. It has also been found that students' expectations of the course objectives

influence their perceptions of the course, even independent of what they actually encounter (Kirschner, Meester, Middelbeek, & Hermans, 1993). In spite of these results, research on students' expectations of a learning environment has lain fallow. More general psychological literature about expectations, however, indicates two reasons for taking the role of expectations in education more seriously: (a) Expectations affect the subsequent perception of a learning environment and so determine its effectiveness, and (b) expectations affect students' motivation, engagement, and investment of effort in learning.

### Expectations and Perceptions

The influence of expectations on students' perceptions of a learning environment is highly relevant because perceptions determine students' study behavior and, consequently, their performance and the effectiveness of the environment (Entwistle, 1991). Expectations can bias perceptions in three different ways. First, expectations bias information-gathering processes because they direct the learner's attention to information that is either consistent or clearly inconsistent with the expectations themselves. Both consistent and inconsistent information is more likely to be noticed, which leads to selective perception (Olson et al., 1996).

Second, expectations bias the interpretation of information because information is likely to be interpreted in a way that is consistent rather than inconsistent with expectations (Olson et al., 1996). A study on expectations of students' capabilities (Murray, 1996) has shown that ambiguous, stereotyped information about race, class, and gender affects the perceiver's estimates of the student's performances. Another example of the expectancy confirmation bias is found in diagnosing learning disabilities (Gnys, Willis, & Faust, 1995). Diagnostic decisions of school psychologists were found to be partly based on irrelevant information and false beliefs. Expectations heightened attention for illusory congruent characteristics in students' test scores and guided the interpretations and diagnoses.

Third, expectations bias subsequent behavior. People are likely to behave in a manner that is consistent with their expectations (Olson et al., 1996). A well-documented example of this phenomenon is learned helplessness (Seligman & Mayer, 1967)—the relinquishing of proactive behaviors when experiencing lack of control over the environment. Symptoms of learned helplessness have also been shown in educational contexts in which students gave up trying to perform when they did not see themselves as capable of reaching success (Craske, 1988). In addition to this direct effect on behavior, expectations may even shape the environment. People tend to behave in such a way that their behavior optimally matches their expectations, and thus, they create what they expect, a phenomenon known as a self-fulfilling prophecy (Merton, 1948). Research has shown that teachers, told that a class was highly intelligent, consequently expected higher performances, which subsequently resulted in higher student performances (the "Pygmalion in the classroom" experiment, Rosenthal & Jacobson, 1968).

Applied to education, adequate or inadequate expectations may have far-reaching effects. A student entering a learning environment with high expectations of finding certain characteristics there (e.g., student autonomy) will look for information consistent with the expectations, interpret this information in such a way that it

supports the expectations, and behave in a way that is consistent with these expectations. This student is likely to have more positive perceptions than another student entering the same environment with low expectations of autonomy because that student will mainly attend to stimuli supporting the low expectations and will interpret stimuli and behave in a way consistent with low expectations. The student with low expectations for student autonomy, consequently, will display less autonomic behavior and a more passive attitude. In contrast, the student with higher expectations is more likely to find stimuli for autonomous behavior and will tend to be more proactive. In short, students in the same learning environment are likely to perceive it differently and to behave differently, depending on their *a priori* expectations of it.

Our study focused on the effects of students' expectations of a new learning environment on their later perceptions by addressing the following research questions: (a) Do expectations of a learning environment predict how the future environment is perceived? and (b) Is students' prospective dissatisfaction associated with the extent of actual dissatisfaction they experience in a learning environment?

### Expectations, Motivation, and Learning

Investigating students' expectations is not only relevant because expectations are related to perceptions but also because research reveals that expectations affect engagement, motivation, and investment of effort. According to the expectancy-value model (Eccles & Wigfield, 2002; Wigfield & Eccles, 2000), expectations and confidence or doubt about the attainability of the personal values influence different aspects of behavior, such as effort, persistence, and performance. These findings imply that students expecting a learning environment that corresponds with their desired environment—which means low prospective dissatisfaction—feel relatively confident and positive, which results in higher learning motivation in the future environment (see also Carver & Scheier, 2001). In contrast, students expecting a learning environment that is very different from their desired environment experience doubt and are in a negative mood, which results in low motivation and disengagement. This finding is in line with cognitive dissonance theory (Festinger, 1957), which states that inconsistencies between cognitions, feelings, and behaviors evoke a negative internal state that people try to reduce whenever possible. Cognitive dissonance is a fundamentally motivational state (Elliot & Devine, 1994), and thus, it is likely that dissonances that students experience in education will have negative motivational effects.

Consequently, a relation between expectations of a learning environment and motivation can be anticipated. More specifically, literature indicates that expectations of at least some characteristics of a learning environment can be hypothesized to be related to motivation. Contextualized and meaningful subject matter results in gains in motivation and involvement when compared with outcomes for abstract and decontextualized learning content (Cordova & Lepper, 1996). Recognizing the utility of course content leads to higher intrinsic motivation and better study habits (Simons, Dewitte, & Lens, 2004). Also, learning goals serving a directive function lead to greater investment of effort, positively affect persistence, and motivate the learner (Locke & Latham, 2002).

Besides the relation of the learning environment to motivation, students' *perceptions* of a learning environment have also been shown to be related to several other learning-related student characteristics (e.g., Luyten, Lowyck, & Tuerinckx, 2001; Wierstra & Beerends, 1996), especially to conceptions of learning (Tsai, 2000) and affective processing strategies (Könings, Brand-Gruwel, & van Merriënboer, 2005a). Motivation is only one aspect of a broader range of student characteristics that might be related to expectations. Vermunt (1996; Vermunt & Vermetten, 2004) defined five clusters of components of student learning: motivational orientations, conceptions of learning, affective processing strategies, information processing strategies, and regulation strategies. The current study explored how students' expectations relate to all components of these five clusters of learning-related characteristics. As perceptions have been shown to be related to more student characteristics than motivation alone, the same may also be true for expectations. No earlier research has focused on this aspect. Therefore, in addition to the two research questions defined earlier in *Expectations and Perceptions*, we investigated the following second set of research questions: (c) Are students' expectations of a learning environment associated with their motivational orientation and other student characteristics? and (d) Is students' prospective dissatisfaction associated with motivational orientation and other student characteristics?

### Expectations, Perceptions, and the Development of Student Characteristics

In addition to the relation between expectations and student characteristics, it is important to investigate the relation between possible differences in expectations and later perceptions (i.e., meeting expectations vs. disappointment with the environment) and the development of student characteristics. Carver and Scheier (2001) predicted strong declines in engagement in cases in which disappointment is encountered. For individuals who begin with high positivism and high engagement and who then experience situations that temper this positivism, engagement slowly decreases for a while. But at some point, a small decrease in the level of positivism produces an abrupt drop in the level of engagement.

So there are indications that the degree to which students' expectations are met influences the development of their learning-related student characteristics, like engagement or motivation. Therefore, the third set of research question is as follows: (e) Is the perceived learning environment in line with students' expectations? and (f) What is the relation between the mismatch in students' expectations and later perceptions and the developments in their learning-related characteristics?

### Powerful Learning Environments

This study investigated student expectations, perceptions, and learning-related characteristics in the context of powerful learning environments (PLEs). Such learning environments promote acquiring high-quality knowledge, problem-solving skills, self-directed learning skills, and transferability of knowledge and skills (see De Corte, Verschaffel, Entwistle, & van Merriënboer, 2003, and Könings, Brand-Gruwel, & van Merriënboer, 2005b, for an overview). Expectations with respect to five characteristics, described in the literature as fundamental to PLEs, were studied in more detail. First, PLEs should contain complex, realistic, and challenging learning tasks (van Merriënboer & Paas, 2003). Second, learning in a PLE is not directed toward reproduction of knowledge but toward an active process of making sense of the subject matter and creating mental models, which can be reused in new problem situations (Collis & Winnips, 2002; Moreno & Mayer, 1999). Third, a self-directed and independent way of learning and thinking is stimulated by gradually transferring the responsibility for the learning processes from the instructional agent to the students themselves (Vermunt, 2003). Fourth, through the inclusion of small groups, collaborative work, and ample opportunities for interaction, PLEs give students an active and constructive role in the learning process (van Merriënboer & Paas, 2003). Fifth, learning goals and task demands are clear as they direct learning strategies (Broekkamp, van Hout-Wolters, Rijlaarsdam, & van den Bergh, 2002).

The proposed concepts involved in the current study are depicted in Figure 1. At the first assessment time (T1), students' expectations of a new learning environment and their prospective

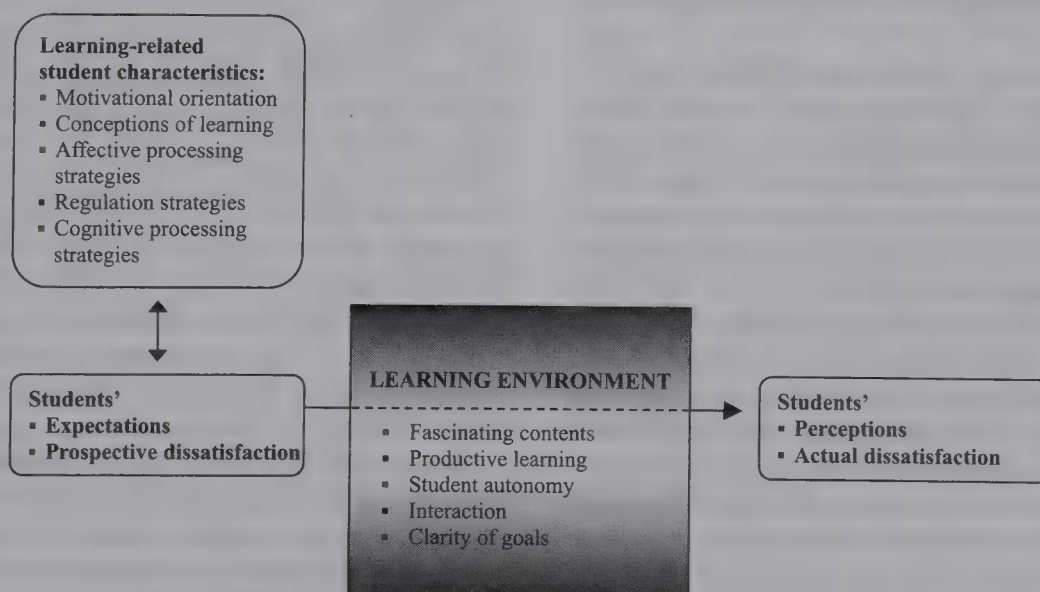

Figure 1. Visualization of the variables involved in the study.

dissatisfaction with it were measured on five characteristics of the environment. Additionally, their learning-related characteristics, like motivation, were investigated. Students reported on their perceptions and actual dissatisfaction with the learning environment after 1 year of experience (T2) and again after 2 years (T3). Relations among measures at T1, T2, and T3 were investigated as well as relations between expectations and student characteristics at T1. Finally, possible discrepancy between expectations at T1 and perceptions at T2 (i.e., disappointment) and the development of learning-related student characteristics was examined.

## Method

### Participants

At the first measurement (T1), the sample consisted of 842 students in the 9th grade (mean age = 15.27 years,  $SD = 0.52$ ) from five secondary schools in the Netherlands who were attending either senior general education (i.e., a 5-year program, preparing for higher professional education) or preuniversity education (i.e., a 6-year program, preparing for university education) classes. They were on the eve of participating in an innovative PLE in Dutch secondary education called the Second Phase. One year later (T2), the sample consisted of 1,146 student in the 10th grade, 727 of whom already had participated at T1. At T2, all students had participated in the innovative environment for 1 year. At T3, the sample consisted of 704 students in the 11th grade from four schools: 433 students participated at all three measurement moments; 181 at T2 and T3; 16 at T1 and T3, and 74 at T3 only. At T3, the 11th graders had studied in the learning environment for about 2 years. In total, 1,335 students participated in the study (50.6% girls, 49.4% boys).

The increase in the number of participants at T2 was partly due to one school's decision to allow only half of the students (i.e., classes) to participate at T1 of this study. One year later (T2), however, all 10th graders of this school participated. Furthermore, about 200 of the newly included participants at T2 were repeaters from an earlier cohort (i.e., the first year). About 20 students at T2 had been absent during data collection at T1. The attrition at T2 was likely due to incidental absence of students and nonpromotion from 9th to 10th grade.

The decrease in the number of participants at T3 was partly due to nonpromoted students who left the program and partly due to one school's decision to refrain from further data collection at T3. Because at each measurement (both at T2 and at T3), the nonpromoted students of an earlier cohort were added to the sample, a better representation of the population was created, and unwanted shifts or biases in the sample were avoided.

The achievement level of the participating schools on the general examination indicates that they are representative of schools in the Netherlands, with one school at the senior general education level scoring greatly above the national average and two schools at the preuniversity level scoring slightly above the average (Onderwijsinspectie [Dutch Inspection of Education], 2006). The percentage of students from cultural minorities at the participating schools ranged from 0.00% to 1.33% (national average is 2.55%; W. Wieldraaijer, Centraal Financiële Instellingen [Central Financial Institution], personal communication, January 8, 2007).

### Materials

*The learning environment.* The context of this study is a nationwide innovation in Dutch secondary education called the Second Phase (Ministerie van Onderwijs, Cultuur, en Wetenschap [Dutch Ministry of Education, Culture, and Science], n.d.; Stuurgroep Profiel Tweede Fase Voortgezet Onderwijs [Steering Committee for the Profile for the Second Stage of Secondary Education], 1995; Veugelers, de Jong, & Schellings, 2004). All schools in the Netherlands had to participate in this innovation. The Second Phase requires students to independently acquire skills and knowledge to better prepare them for higher professional education and university. Students learn in a self-directed way with possibilities for collaborative learning. There is more room for individual differences than in the traditional educational system, and teachers have to take these differences into account. The teacher's role is more like that of a coach and less like that of an instructor, which creates more possibilities for interaction between students and the teacher. The learning process is not only directed to knowledge acquisition but also to the selection and processing of the vast amounts of information available today. Furthermore, learning content is actualized and broadened because building a broad general knowledge base is an important goal of the Second Phase. Courses are clustered in profiles of closely interconnected topics (e.g., science and health, economics and society) that are meant to enable better integration of the subjects and lead to a better preparation for higher professional education and university. In addition, the coherence between knowledge and skills and the application of knowledge in subject-matter domains are emphasized.

The objective characteristics of the implementation of the Second Phase on the schools participating in this study are beyond the scope of this article. However, research has shown that—in general—its implementation with respect to stimulating student autonomy and differentiation are not convincingly perceived by teachers (Könings, Brand-Gruwel, & van Merriënboer, 2007). Teachers also do not perceive much freedom to deviate from lesson programs and regret this lack of freedom (Veugelers et al., 2004).

*Inventory of Expected Study Environment—Extended (IESEE) and Inventory of Perceived Study Environment—Extended (IPSEE).* The IESEE measures students' expectations of a forthcoming learning environment and their prospective dissatisfaction with regard to that environment. It is a parallel version of the IPSEE, which measures students' perceptions of a learning environment and their desires and actual dissatisfaction with regard to the design of the environment. Both IESEE and IPSEE consist of 44 items, partly based on the Inventory of Perceived Study Environment (IPSE; Wierstra, Kanselaar, van der Linden, & Lodewijks, 1999), which was translated into Dutch by the Expertise Center for Active Learning of Maastricht University (Picarelli, Slaats, Bouhuijs, & Vermunt, 2006).

The IESEE/IPSEE items are ordered in five scales (see Table 1) that can be seen as basic characteristics of PLEs. All items contain a statement about one of the characteristics of a learning environment and two statements, one related to the expectation/perception of a characteristic and one related to its desirability, as in the following example:

Table 1

*Internal Consistencies of the Scales of the Inventory of Expected Study Environment—Extended at T1 and the Inventory of Perceived Study Environment—Extended at T2 and T3*

Scale	Description of scale	No. of items	Cronbach's alpha coefficient					
			T1		T2		T3	
			Expectation	Dissatisfaction	Perception	Dissatisfaction	Perception	Dissatisfaction
Fascinating Content	Extent to which learning contents are interesting, challenging, and personally relevant for students	9	.82	.72	.85	.81	.85	.84
Productive Learning	Little emphasis on sole reproduction of learning contents but rather on an active process of making sense of the subject matter and creating mental models	5	.80	.80	.83	.84	.79	.76
Student Autonomy	Self-directedness with regard to contents and way of learning and planning	15	.81	.82	.85	.88	.84	.88
Interaction	Collaboration with peers and interaction with teacher	11	.68	.65	.73	.71	.68	.73
Clarity of Goals	Clarity of instructional goals and task demands	4	.75	.69	.81	.79	.83	.82

Note. T = time of assessment (1, 2, or 3).

Students can decide for themselves how they wish to learn during the course.

(A). I expect this to happen (in the 10th grade)/This happens.

(B). I would like this to happen.

The statements are rated on a 6-point scale, ranging from *totally disagree* (1) to *totally agree* (6). Scores on Statement A give a measure of the student's expectation/perception of the learning environment. Scores on Statement B show what the student desires from the environment. For the IESEE, the difference between the scores on Statements B and A is defined as a measure of the prospective dissatisfaction with the forthcoming environment. For the IPSEE, the difference is a measure of the actual dissatisfaction with the perceived environment. Increasing differences indicate increasing dissatisfaction. Small differences indicate low dissatisfaction. It should be noted that low dissatisfaction could be interpreted as high satisfaction, but we used only the term *dissatisfaction* to interpret and present the results in a univocal way.

**Statistics of the IESEE.** Internal consistencies of the IESEE are presented in Table 1 (T1, Columns 1 and 2). The coefficients for the expectation items ranged from .68 for the Interaction Scale to .82 for the Fascinating Content Scale. With respect to dissatisfaction scores, the alpha coefficients ranged from .65 for the Interaction Scale to .82 for the Student Autonomy Scale. In total, 3 of 10 Cronbach's alpha coefficients were above .60; 2 were above .70, and 5 were above .80. To examine whether the five scales were sufficiently independent to warrant separate consideration, we computed pairwise correlations between the scales. Of the 20 correlations (10 over expectation data and 10 over prospective dissatisfaction data), all were below .50; the implication of this finding is that

less than 25% of the variation on one scale can be explained by variation on the other scale. In addition, the tolerance was computed as a check for possible collinearity between scales. The tolerance measure, which has a range from 0 to 1, indicates serious collinearity if the values are below .10. It was computed separately for each of the five scales for perception and dissatisfaction data: The lowest value was .58, with six of the values being above .60. There was no statistical objection to consider the five IESEE-scales separately.

**Statistics of the IPSEE.** Internal consistencies were computed for all five scales for the perception items and the actual dissatisfaction scores separately at T2 and T3 (see Table 1, Columns 3–6). For the Fascinating Content Scale, the coefficients ranged between .81 and .85; for the Productive Learning Scale, between .76 and .83; for the Student Autonomy Scale, between .84 and .88; for the Interaction Scale, between .68 and .73; and for the Clarity of Goals Scale, between .79 and .83. In total, only 1 of 20 Cronbach's alpha coefficients was between .60 and .70; 6 were between .70 and .80, and another 13 were above .80. As for the IESEE-scales, correlations between the scales were computed over perception data and dissatisfaction data. At T2, 15 of 20 correlations were below .50, 4 were between .50 and .60, and 1 was above .60. The lowest tolerance value found at T2 was .45. Of the remaining values, 4 were above .50, and another 4 were above .60.

For T3, 15 correlations between the scales were below .50, and 5 were between .50 and .60. The lowest tolerance value was .49; 4 values were above .50, and another 4 were above .60. Thus, there are no statistical objections to considering the five scales separately.

**Inventory of Learning Styles for Secondary Education (ILS–SE).** The ILS questionnaire was originally developed to measure higher education students' learning styles (Vermunt, 1992) and was

adapted for students in secondary education by Vermunt, Bouhuijs, and Picarelli (2003). The questionnaire measures learning-related characteristics of students on the basis of their usual way of learning. The ILS-SE consists of 100 items. Because of the results of factor analyses, we decided to exclude a single item because of a small factor loading ( $< .40$ ). The remaining 99 items were divided in five clusters: Processing strategies (cognitive activities students use to process learning contents), regulation strategies (the way students regulate their own learning process), motivational orientations (personal goals or motives students have for learning and going to school), conceptions of learning (mental models about learning), and affective processing strategies (emotional aspects of learning). Each of the five clusters contains several scales, which are presented in Table 2.

For each item in the ILS-SE, students rate the degree to which a statement corresponds to their own learning on a 5-point scale. Information about internal consistencies of the scales at T1 and T2 is included in Table 2. At T1, Cronbach's alpha ranged from .58 for the Intrinsic Motivation and Certificate-Oriented Motivation Scales to .87 for the Motivation/Concentration Problems and Fear of Failure Scales. At T2, the coefficients ranged from .63 for the Certificate-Oriented Motivation Scale to .87 for the Fear of Failure Scale. In total, 2 of 32 Cronbach's alpha coefficients were .58, 7 were above .60, 13 were above .70, and 10 were above .80, all of which are acceptable. By computing correlations and tolerance values, we tested the independence of the 16 ILS-SE-scales. Table 3 shows the correlations between the scales. It can be seen that 116 of the correlations were below .50, 3 were between .50 and .60,

Table 2  
*Descriptions and Internal Consistencies of the Scales of the Inventory of Learning Styles for Secondary Education at T1 and T2*

Scale	Description of scale	No. of items	Cronbach's alpha coefficient	
			T1	T2
Processing strategy				
Deep processing	Relating and structuring knowledge elements and critical processing of information	12	.84	.84
Stepwise processing	Memorizing, rehearsing, studying information in detail	8	.81	.80
Regulation strategy				
Self-regulation	Regulation of own learning process through activities like planning, monitoring, reflecting, and taking initiatives with respect to learning contents	8	.71	.71
External regulation	Learning processes to be regulated by external sources (i.e., books, teacher)	6	.68	.66
Lack of regulation	Difficulties with regulating learning and processing contents effectively	4	.66	.71
Learning orientation				
Intrinsic motivation	Learning because of interest in learning content and the desire to develop oneself	4	.58	.67
Certificate oriented	Learning for passing tests, gaining high grades, and obtaining certificates	5	.58	.63
Vocation oriented	Learning for future study and professions	4	.73	.77
Ambivalent	Doubtful, uncertain attitude toward own capacities and chosen courses	5	.75	.74
Conception of learning				
Construction and use of knowledge	Learning as constructing one's own knowledge, making it concrete, and applying it	8	.82	.81
Intake of knowledge	Learning as taking in information and memorizing or reproducing it	4	.64	.64
Cooperative learning	Preferring to learn in cooperation with fellow students	3	.70	.76
Stimulating education	Learning as a process continuously driven by teachers or textbooks	5	.78	.79
Affective learning strategy				
Motivation/concentration problems	Difficulty with concentrating and staying motivated during learning, being easily distracted, and sometimes postponing assignments	8	.87	.86
Fear of failure	Experiencing stress during learning, especially in testing situations, and having a negative self-image	8	.87	.87
Keeping a good state of mind	Having a positive opinion of own capacities, being self-confident, and performing activities to stay motivated and concentrated	8	.72	.71

Note. T = time of assessment (1, 2, or 3).

\*  $p < .05$ . \*\*  $p < .01$ .

and only 1 was slightly above .60. The lowest tolerance value was .40, with 12 values above .60. Thus, there was no statistical objection to considering the 16 ILS-SE scales separately.

### Procedure

At T1, the participants filled out the IESEE and the ILS-SE. At T2, they filled out the IPSEE and the ILS-SE. At T3, they only filled out the IPSEE. Preceding the completion of a questionnaire, students received a short oral instruction about the goal and content of the questionnaire and about the way items had to be scored. This instruction was repeated on the first page of each questionnaire. The IESEE/IPSEE took between 30 and 40 min to complete; the ILS-SE took between 20 and 30 min. The participants filled out the questionnaires during regular school hours.

### Data Analysis

A maximum of 25% of missing values was accepted to compute the mean scores for each scale of the IESEE, IPSEE, and ILS-SE. If at least 75% of the items of a scale were filled out, these items were used to compute the mean score of that scale. For each scale, we could calculate a mean score using at least 95% of the participants. Dissatisfaction scores of the IESEE/IPSEE were computed as the difference between the desirability score and the expectation/perception score. To answer the research questions, we focused on students who had a positive attitude toward PLEs. This means that we analyzed only data of students who desired a particular characteristic of a learning environment to be more strongly implemented than they expected or perceived (i.e., desire - expectation/perception  $\geq 0$ ). In fact, there were also students who desired particular aspects of PLEs to be less strongly implemented, but these were rather small groups (< 10% of all students for three scales, < 20% for two scales).

Since the longitudinal design had a nested data structure, with participants nested in classes (i.e., year groups) and classes nested in schools, we expected both serial correlations due to repeated

measurements and intraclass correlations due to the multilevel structure. Data were analyzed with a longitudinal mixed model: Repeated measures were considered to be nested in participants, and participants were considered to be nested in classes. Because the number of schools was too small to permit inference to the population of schools, school was included as a fixed factor in the model to correct for correlations in the data due to nesting within schools. Thus, it is assumed that the five schools were representative of the wider population of schools. School and/or class was only included in the model if the effects was significant at a level of  $p < .10$ .

Apart from accounting for the multilevel structure of the data, the longitudinal mixed model analysis has two other advantages over traditional repeated measures analysis of variance (ANOVA). First, repeated measures ANOVA assumes that the residual variation can be described by a covariance structure known as sphericity. This is a highly restrictive assumption that is seldom realistic in the case of repeated measures. The longitudinal mixed model permits the specification of more realistic covariance structures. We opted for an unstructured covariance matrix, posing no restrictions on the values of residual variances and covariances. Second, repeated measures ANOVA discards each participant with a missing value on any of the three measurements. In contrast, the longitudinal mixed model makes use of maximum likelihood estimation. Under the assumption that cases are missing at random (MAR), participants with missing data on one or two measurements can still be used for estimation purposes. The MAR assumption is plausible in our case, so that mixed model analysis allowed for a more efficient use of the available data while still yielding unbiased estimates of effects.

A specific problem for analyzing data to answer Research Questions a, b, e, and f was the correction for class effects. Class composition changed over the time periods so that the same pupil could belong to three differently composed classes. We circumvented this problem by trying out a maximum of three different class corrections for each separate model. We first tried class as a

random factor by using the classes as composed at T1, then classes as composed at T2, and finally classes as composed at T3. In principle, this procedure could result in more significant class effects to be reported, but in practice, this did not pose a problem because the estimates of the fixed effects were unbiased, and the standard errors only marginally changed under the different class corrections. The tables that will be discussed in the Results section only report standard errors corrected for school effects (if relevant). If a significant class effect changed a parameter estimate from significant to nonsignificant or vice versa, we will explicitly discuss it in the text. In the following section, only results significant at a level of  $p < .01$  are reported.

Results

Table 4 presents the means and standard deviations of expectation scores (T1), perception scores (T2 and T3), and dissatisfaction scores (T1, T2, and T3).

Relationships Between Students' Reports on Different Measurement Moments

To investigate how expectations of a learning environment predict perceptions of the future environment and how prospective dissatisfaction predicts actual dissatisfaction (i.e., Research Questions a and b), we conducted mixed model regression analyses to examine mutual relations between expectation scores at T1, perception scores at T2, and perception scores at T3. To investigate the relation between expectation scores at T1 and perception scores at T2, we tested a model with only data from T1 and T2: the perception score at T2 as a dependent variable and the expectation score at T1 as an independent variable. We examined the relations between expectation scores (at T1) and perception scores at T2 and T3 by building a model with perception scores at T3 as dependent variable and expectation scores at T1 and perception scores at T2 as independent variables. Testing this model provided insight in the relation between scores at T1 and T3 and between scores at T2 and T3. Because perception scores at both T2 and T3 were included in the model, the regression coefficient of the score at T2 was corrected for the score at T3 and vice versa. The regression coefficients represent the size of the unique part of the relation between the dependent and independent variable.

*Expectation and perception scores.* The left side of Table 5 presents the results of analyzing the mutual relations between expectation scores at T1 and perception scores at T2 and T3. The expectation scores at T1 had a significant positive effect on perception scores at T2 for all scales. Thus, the higher the expectation scores, the higher the perception scores at T2. Perception scores at T2 also had a significant positive effect on perception scores at T3. But as can be seen from Table 5, the direct effect of expectation scores (T1) on perception scores at T3 was nonsignificant for two scales and relatively small for the other scales. This result is likely due to the mediating role of the perception scores at T2. By including perception scores at T2 in the analyses, we corrected the results for this potential mediator and showed the size of the unique relation between scores at T1 and T3.

*Dissatisfaction scores.* Results for relations between dissatisfaction scores at T1, T2, and T3 (see the right side of Table 5) show that, for all scales, prospective dissatisfaction at T1 had a positive effect on actual dissatisfaction at T2, and dissatisfaction at T2 had a positive effect on dissatisfaction at T3. Prospective dissatisfaction at T1 had a direct positive effect on actual dissatisfaction scores at T3 on two of the scales, indicating a unique relation between the dissatisfaction scores at T1 and T3 for Fascinating Content and Clarity of Goals Scales.

In summary, the results for Research Questions a and b show robust relations between expectations and later perceptions. The higher students' expectations before entering the new learning environment, the higher their subsequent perceptions later on. Prospective dissatisfaction scores were positively related to actual dissatisfaction scores with the perceived learning environment.

Relationships Between Students' Reports at T1 and Learning-Related Student Characteristics

To investigate how expectations of the future learning environment are related to motivation and other learning-related student characteristics and how prospective dissatisfaction is related to these student characteristics (i.e., Research Questions c and d), we conducted mixed model regression analyses to analyze the relations between IESEE scores at T1 and learning-related student characteristics at T1. The learning-related student characteristics were included as independent variables in mixed model regression analyses. A backward procedure was used, in which the less

Table 4

significant variables were removed one by one, until all included variables were significant ( $p < .01$ ).

**Expectation Scores and Learning-Related Student Characteristics.** Table 6 presents the results on relations between expectation scores and learning-related student characteristics. As can be seen from this table, some student characteristics were related to expectation scores on several scales. These will be described in more detail. Intrinsic motivation was positively related to students' expectation scores for the Fascinating Content, Student Autonomy, Interaction, and Clarity of Goals Scales. The conception of learning as the construction and use of knowledge was also frequently related to high expectation scores: The stronger this conception, the higher students' expectations were with respect to Fascinating Content and Student Autonomy Scales. Furthermore, the use of external regulation strategies was positively related to expectation scores for Interaction and Clarity of Goals Scales. Finally, the report of fear of failure was negatively related to expectation scores for Student Autonomy and Clarity of Goals Scales. Thus, the higher the reported fear of failure was, the lower the expectations on these scales.

With respect to the formulated hypotheses about the relation between motivation and expectations for the Fascinating Content and Clarity of Goals Scales, the results show that motivational orientations were, for those scales, indeed related to expectations. For both scales, intrinsic motivation was related to holding higher expectations on how the future learning environment would look.

Expectations for Fascinating Content were negatively related to problems with motivation and concentration, while the ambivalent motivational orientation especially was negatively related to expectations about Clarity of Goals. As can be seen from Table 6, expectation scores for both scales were also related to some other learning-related student characteristics.

In summary, the results show that learning-related student characteristics were related to expectations of the future environment and, mostly, in a consistent fashion related to either higher or lower expectation scores. Especially, students reporting fear of failure tended to expect a less powerful learning environment, while students with an intrinsic motivational orientation and students with a constructivist conception of learning tended to expect the future environment to be a more powerful one.

**Prospective Dissatisfaction Scores and Learning-Related Student Characteristics.** Table 7 presents results of mixed model regression analyses on the prospective dissatisfaction data. Some of the student characteristics were often related to dissatisfaction scores, either positively or negatively. An intrinsic motivational orientation was negatively related to prospective dissatisfaction scores for four scales. The stronger students' intrinsic motivation for learning was, the lower their prospective dissatisfaction scores on the Fascinating Content, Productive Learning, Student Autonomy, and Clarity of Goals Scales. Also, the conception of learning as construction and use of knowledge was related to low prospec-

Table 6

<sup>a</sup>Corrected for school effects.

tive dissatisfaction, especially for Productive Learning and Interaction Scales.

Positively related to prospective dissatisfaction was an ambivalent motivational orientation: The stronger students' ambivalent motivation, the higher their prospective dissatisfaction scores for the Fascinating Content, Interaction, and Clarity of Goals Scales. Problems with motivation and concentration were related to higher prospective dissatisfaction scores for Fascinating Content, Productive Learning, and Student Autonomy Scales. Another three student characteristics were also related to higher prospective dissatisfaction scores: the conception of learning as intake of knowledge, the certificate-learning orientation, and the affective strategy keeping good state of mind (each for two IESEE scales).

The analyses of prospective dissatisfaction scores and learning-related student characteristics reveal that some student characteristics, and particularly intrinsic motivation, are related to low prospective dissatisfaction scores. Other student characteristics, such as an ambivalent motivational orientation and problems with motivation and concentration, are related to high prospective dissatisfaction scores.

Summarizing, results for Research Questions c and d show that learning-related student characteristics are related to expectations. Fear of failure was frequently related to lower expectations, whereas intrinsic motivation and a conception of learning as the construction and use of knowledge were related to higher expectations. Prospective dissatisfaction was often related to an ambivalent motivational orientation and problems with motivation and concentration. Intrinsic motivation was frequently related to low prospective dissatisfaction.

### Mismatch Between Expectations and Perceptions and Development of Student Characteristics

To examine whether students' perceptions of an environment are in line with their expectations of it (i.e., Research Question e), we used a longitudinal mixed model analysis. For testing longitudinal effects over time,  $F$  values were computed, and for identifying the exact differences among the three times of measurement, pairwise comparisons with Bonferroni correction were conducted, and Cohen's  $d$  effect size was computed. Only differences with  $d > .20$  are described in the text.

For investigating the relation between the size of the mismatch between expectations and later perceptions and the development of learning-related student characteristics in the same period (i.e., Research Question f), we conducted mixed model regression analyses in the same way as the analyses for Research Questions c and d. The mismatch between expectation scores at T1 and perception scores at T2 ( $T2 - T1$ ) ranged from  $-5$ , indicating a large decrease in scores from T1 to T2 and strong disappointment, to  $+5$ , indicating a large increase in scores from T1 to T2 and thus much higher perceptions than previously expected. Changes in each learning-related student characteristic ( $T2 - T1$ ) were included as independent variables in the model. By using a backward procedure, we built a model that only contained variables that were significant at  $p < .01$  ( $p_{\text{school/class}} < .10$ ).

**Expectation and Perception Scores.** Table 8 shows the results of the mixed model longitudinal analyses on expectation and perception scores. The results of the  $F$  tests show that significant longitudinal effects existed on all scales of the IPSEE ( $p < .01$ ). The differences between expectation scores (T1) and perception scores (T2) show that the scores decreased on four of the five

Additional correction for class effects did not change the significance of the result, unless stated in text.

<sup>a</sup>Corrected for school effects.

scales, indicating disappointing perceptions compared with the expectations. The effect size was large for the Student Autonomy Scale (.84). For most scales, the differences between perception scores at T2 and T3 showed no significance. An increase of perception scores from T2 to T3 was found only for the Productive Learning Scale. Apparently, students perceived this element of the environment as being present more strongly at T3 than at T2. Scores on the Productive Learning Scale, notably, increased year after year (from T1 to T2, and from T2 to T3). However, the most striking result is the large decline of expectation scores at T1 and perception scores at T2 on the majority of the scales. Apparently,

the perceived learning environment did not meet students' expectations.

*Relations Between Disappointment and Development of Student Characteristics.* Results revealed that a decrease from expectation scores (T1) to perception scores (T2) on the Fascinating Content Scale was related to a decrease in intrinsic motivation ( $B = .24$ ;  $SE B = .05$ ;  $\beta = .20$ ), a decrease in reported use of deep processing strategies ( $B = .20$ ;  $SE B = .05$ ;  $\beta = .13$ ), and an increase in fear of failure ( $B = -.21$ ;  $SE B = .04$ ;  $\beta = -.18$ ) from T1 to T2. Thus, the larger the disappointment, the more intrinsic motivation and use of deep processing strategies decreased, and

Table 8  
Results of Mixed Model Analyses on Longitudinal Data of Expectations (T1) and Perceptions (T2 and T3)

Scale	F	df	T2-T1			T3-T2		
			$\Delta$	SE	d	$\Delta$	SE	d

Student Autonomy	243.21*	2, 582.42	-.59*	.03	.84	.07	.03	.10
Interaction	65.90*	2, 501.33	-.28*	.03	.44	.05	.02	.08
Clarity of Goals	45.80*	2, 428.35	-.33*	.04	.35	.02	.04	.02

Note. Scales were from the Inventory of Expected Study Environment—Extended and the Inventory of Perceived Study Environment—Extended. Standard errors were based on estimation of fixed effects without correction for class effects, but with correction for school effects (if  $p_{\text{school}} < .10$ ). Additional correction for class effects did not change the significance of the result, unless stated in text. T = time of assessment (1, 2, or 3).

\*  $p < .01$ .

the more fear of failure increased. For the Student Autonomy Scale, disappointment was related to an increase in fear of failure ( $B = -.15$ ;  $SE B = .04$ ;  $\beta = -.14$ ) and a decrease in deep processing ( $B = .16$ ;  $SE B = .05$ ;  $\beta = .11$ ). For the Interaction Scale, disappointment was related to a decrease in deep processing strategies ( $B = .16$ ;  $SE B = .05$ ;  $\beta = .13$ ), a decrease in considering learning as a cooperative activity ( $B = .08$ ;  $SE B = .03$ ;  $\beta = -.11$ ), and an increase in the ambivalent motivational orientation ( $B = -.10$ ;  $SE B = .04$ ;  $\beta = .10$ ). For the Clarity of Goals Scale, disappointment was related to a decrease in intrinsic motivation ( $B = .18$ ;  $SE B = .05$ ;  $\beta = .13$ ) and in keeping a good state of mind ( $B = .20$ ;  $SE B = .06$ ;  $\beta = .13$ ). Productive Learning was the only scale showing an increase in scores from T1 to T2. Exceeding the expectations for the Productive Learning Scale was related to a decrease in the conception of learning as intake of knowledge ( $B = -.15$ ;  $SE B = .05$ ;  $\beta = -.10$ ) and a decrease in fear of failure ( $B = -.15$ ;  $SE B = .06$ ;  $\beta = -.10$ ).

Summarizing, results for Research Questions e and f showed that students' perceptions of the new learning environment on most scales did not meet their expectations and that disappointment was related to undesirable changes in learning-related student characteristics, especially to an increase in fear of failure, a decrease in deep processing, and a decrease in intrinsic motivation.

### Discussion

The current study aimed to shed light on the role of expectations in education, especially expectations students have of a future learning environment. Because students move to new learning environments several times during their school career, it is relevant to gain insight in their expectations and subsequent perceptions of these new environments and to investigate how learning-related student characteristics relate to those expectations.

Research Questions a and b focused on the relations between expectations of how the future learning environment would look and later perceptions and relations between prospective dissatisfaction and actual dissatisfaction while perceiving the environment. Expectations were positively related to subsequent perceptions of the environment for all measured aspects of the environment. Thus, the higher the expectations beforehand, the higher the perceptions later on, and the lower the expectations beforehand, the lower the perceptions later on. Perceptions measured at the second and third time were also clearly positively related. Additionally, prospective dissatisfaction with the new environment was related to actual dissatisfaction after 1 year, and dissatisfaction after 1 year of participating in the environment was related to dissatisfaction after 2 years.

The relations between expectations/perceptions and dissatisfaction over time may well be explained by the cognitive biases described in the introduction of this article (see, e.g., Olson et al., 1996). People selectively pay attention to information consistent with their expectations and also interpret this information in such a way that their expectations are confirmed. Additionally, people create self-fulfilling prophecies because they behave in agreement with their expectations.

For Research Questions c and d, relations between expectations and learning-related student characteristics were investigated, as well as the way prospective dissatisfaction was related to those characteristics. Having an intrinsic motivational orientation and

conceiving of learning as the construction and use of knowledge are both related to higher expectations of the new environment. Reporting fear of failure frequently relates to low expectations; thus, students who report a strong fear of failure are more reserved in their expectations of the future environment. These findings confirm the assumed relation between motivation and expectations but also show that expectations are influenced by conceptions of learning and affective processing strategies.

Prospective dissatisfaction with the new learning environment is negatively related to intrinsic motivation for learning; that is, intrinsically motivated students think they will be satisfied with the new environment. On the contrary, motivation/concentration problems and an ambivalent motivation are strongly related with high prospective dissatisfaction; students with these characteristics think they will be unhappy with the new environment.

The finding that high expectations are related to high intrinsic motivation and an active view on learning is in agreement with the relation between positivism and "engagement," proposed by Carver and Scheier (2001). Low expectations are especially related to fear of failure. It would be an oversimplification to consider this as a form of "low engagement." Students with fear of failure prefer a high degree of structure, clearness, stability, and continuity in their learning environment (Hermans, 1975). They are averse to unexpected and unfamiliar situations. Low expectations of the new and thus unfamiliar learning environment are better understandable in this context.

The finding that high prospective dissatisfaction with the new environment is, among other things, related to problems with motivation and concentration and to an ambivalent motivational orientation fits in the expectancy-value model (Carver & Scheier, 2001; Eccles & Wigfield, 2002). That model holds that discrepancies between expectations and personal values influence persistence and the amount of effort invested in learning and may induce a sense of doubt or negative thinking. Ambivalent motivation and problems with motivation and concentration are clear signals of doubt and negativism, and they thus may indicate a lack of persistence and unwillingness to invest effort in learning. The finding that intrinsic motivation for learning relates to low prospective dissatisfaction is in agreement with results on positive thinking and feeling confident, as described in the literature. Literature about expectations and motivation proposes causality between expectations and motivation, but it is well imaginable that the effect is bidirectional. A well-motivated student may recognize the utility of course contents more than a less-motivated student. Since the main focus of our study was trying to understand student expectations, we have focused on expectations as dependent variables and investigated whether there are more (or other) student characteristics than motivation that relate to students' expectations and prospective dissatisfaction. We could only test this by including student characteristics as independent variables, to be related to expectations/prospective dissatisfaction on a particular characteristic of the learning environment. In this way, it became clear that, besides motivation, fear of failure and certain conceptions of learning also relate to expectations.

Research Questions e and f concerned possible discrepancies between expectations of the new environment and later perceptions of it. We sought to determine whether students' expectations of an innovative learning environment in Dutch secondary education were met (i.e., Research Question e). Results clearly

show that students' perceptions of the new environment fell short of their expectations. Expectations were higher than the perceptions after 1 year with respect to Fascinating Content, Student Autonomy, Interaction, and Clarity of Goals Scales. The Productive Learning Scale was the only aspect for which perceptions exceeded the expectations after 1 year and for which perceptions increased even further in the second year. This is a positive finding, because the innovative environment indeed aimed to stimulate active processing and application of knowledge, rather than reproductive learning. However, the disappointing perceptions of the other aspects of the environment are worrying. Apparently, the Second Phase is implemented in such a way that students do not perceive its valuable aspects as much as they had expected beforehand. This is problematic because perceptions direct students' learning behavior (Entwistle, 1991), which eventually determine whether educational goals of the environment will be reached.

Results on relations concerning the mismatch between expectations and perceptions and the developments in student characteristics (i.e., Research Question f) indicate that a mismatch is related to negative changes in student characteristics. Disappointment is related to increasing fear of failure, lower intrinsic motivation, and less use of deep processing strategies. Negative effects of disappointment were proposed by Carver and Scheier (2001) and by the expectancy-value model (Eccles & Wigfield, 2002), but our results further refine the nature of these effects.

A first theoretical implication of our findings is that principles from general psychological research on expectations are also applicable to an educational setting, in particular, a setting in which students are confronted with the implementation of a new learning environment. A second implication is that the concept of expectations deserves a much more prominent place in educational research than it has today. As shown in our study, students' expectations of a new learning environment are not automatically in line with later perceptions, and, even more important, expectations strongly influence the way they perceive the environment after it has been implemented. Perceptions are likely to determine students' learning behaviors and, consequently, the effectiveness of the learning environment. Gaining more insight into the role of student expectations is thus of utmost importance in developing guidelines for the design of PLEs, preferably in such a way that students' expectations are taken into account.

A practical implication of our findings is that schools and teachers should carefully prepare their students for curricular changes or innovations. The quality and quantity of information that students receive on the characteristics of a new learning environment before they start to work in it should be carefully determined to help them build proper expectations. If at all possible, disappointing perceptions should be prevented. Students with a high fear of failure are particularly vulnerable in situations of change: They should be given extra support and structure before and during the implementation of a new environment.

A limitation of the current study is that students were always forced to report their expectations of the environment in the questionnaire, regardless of the clearness of their expectations, and it is unknown how students formed their expectations and which sources of information they used to form them. Future research should focus on the origin of the expectations, including the sources that students use to form them (e.g., press, siblings, peers,

parents), in order to gain more insight into the processes yielding the expectations that students reported in this study. This can provide more insight into the nature of expectations in an educational setting and might help researchers to develop a theory of how expectations can best be dealt with in educational design. Furthermore, knowledge about the origin of expectations would provide schools with valuable information that they could use to optimize their preparation of students for curricular changes and innovations. In line with this, future research should also address the question of how the process of forming expectations could be influenced to result in more accurate expectations, that is, expectations that match later perceptions.

To conclude, this study showed that expectations of a learning environment deserve a prominent role in educational research and praxis. Students do not automatically form proper expectations of a new environment such as the Second Phase in Dutch secondary education. Nevertheless, these expectations influence their perceptions of the new environment. Disappointing perceptions are likely to decrease the effectiveness of the environment and are also related to undesirable changes in learning-related student characteristics. More effective approaches are needed to prepare students for large educational changes; such approaches should also take into account differences in individual learning characteristics and related prospective ideas. It would be highly beneficial for educational design if guidelines were developed that took into account students' expectations of curricular changes or innovations.

# Using Argumentation Vee Diagrams (AVDs) for Promoting Argument–Counterargument Integration in Reflective Writing

E. Michael Nussbaum  
University of Nevada, Las Vegas

This study examined a new prewriting tool, argumentation vee diagrams (AVDs), which are used to write reflective opinion essays. AVDs are based on the theoretical concept of argument–counterargument integration, which involves evaluating and integrating both sides of an issue before developing a final conclusion on a controversial question. In a test of the effectiveness of AVDs, 45 undergraduates at a large, southwestern university were randomly assigned to an experimental or control group. Both groups wrote 4 opinion essays over a 4-week period. The experimental group also received training on using the AVDs, including instruction on criteria for weighing arguments. Results indicated that AVD training was effective in enhancing argument–counterargument integration. Furthermore, examination of integration strategies used by participants revealed a new strategy, *minimization*, which was not previously part of E. M. Nussbaum and G. Schraw's (2007) argument–counterargument integration framework. Minimization involves curtailing the importance or extensiveness of a problem or advantage as a heuristic shortcut for weighing advantages and disadvantages. The role of critical questions and argumentation schemata in argument–counterargument integration is discussed.

**Keywords:** argumentation, critical thinking, graphic organizers, thinking skills, writing (composition)

The following is an example of argument–counterargument integration:

One argument for the U.S. invasion of Iraq was the elimination of weapons of mass destruction. Counterarguments included the possibility of destabilizing the region and the huge cost in dollars and human lives. On balance, the counterarguments now appear stronger. There was little evidence for the administration's claims, the costs have been tremendous, and more people than ever are joining terrorist groups. A possible "in-between" solution would have been to use a United Nations force so the United States would not appear to the Muslim world to be an aggressor.

Evaluating arguments for and against a course of action is an essential skill for effective personal and social decision making, as the above example illustrates. The ability to critically combine arguments and counterarguments into an overall final opinion is known as *argument–counterargument integration* (Nussbaum & Schraw, 2007; Nussbaum, Winsor, Aqui, & Poliquin, 2007). Argument–counterargument integration is an important aspect of writing reflective or persuasive essays. This study examined what strategies college students use when asked to engage in argument–counterargument integration. It also examined the effect of training students to engage in argument–counterargument integration using graphic organizers known as *argumentation vee diagrams* (AVDs).

---

## Theoretical Foundations

### *Philosophic Foundations*

Several philosophic frameworks inform contemporary work on argumentation (Nussbaum, 2007). Philosophic models are intended to provide normative standards of good argumentation. Most contemporary models recognize that argumentative reasoning is both defeasible and dialectical. Defeasibility refers to the fact that a good argument is one that can withstand (i.e., defeat) objections (Pollock, 1987). Dialectical arguments are those that are constructed in response to questions or challenges generated by an interlocutor (argumentation can occur among individuals or as part of internal dialogue; see Kuhn, 2005). Philosophers disagree as to whether an argument must be generated dialectically to even qualify as an argument (Finocchiaro, 2005; Johnson, 2002), but most would agree that a good argument must respond to challenges (Erduran, Simon, & Osborne, 2004; Vorebej, 2006).

Naess (1966) proposed that one should analyze arguments by examining the reasons in support of a conclusion (pro-argumentation) and those supporting the opposite conclusion (contra-argumentation). Counterarguments can also show why a pro-argument is weak or flawed; such arguments have also been referred to as *refutations* (Aristotle, 350 B.C.E./1955), *undercutting defeaters* (Pollock, 1987), or *Counter-Cs* (Felton & Kuhn, 2001). Although there is not complete consistency in how various authors use these terms, Kuhn (1991) used the term *rebuttal* to refer to an argument refuting a counterargument, (i.e., a counter-argument to a counterargument; see also Nussbaum & Kardash, 2005). These are all Naess-like models.

Although not necessarily more valid, a more influential model of argument was advanced in the late 1950s by Toulmin (1958), who proposed that arguments made in ordinary discourse have six components: (a) *claim* (i.e., conclusion), (b) *grounds* (response to

the question, "Why?" or "What are your reasons?"), (c) *warrant* (response to the question, "So what?" or "How do your grounds lead to your claim?"), (d) *backing* ("How do you establish the truth of the warrant?"), (e) *rebuttals* (to potential counterarguments or exceptions), and (f) *modal qualifiers* (that qualify certainty in the conclusion). Toulmin initially proposed his model to show that formal logic provided an insufficient basis for judging the strength of arguments. It is unclear whether Toulmin intended his model primarily as a descriptive or normative framework; the model has been used in both ways (e.g., Kelly, Drunker, & Chen, 1998). Descriptively, it has been used as the basis for most argumentation coding systems in educational research (Bell & Linn, 2000; Erduran et al., 2004; Jiménez-Aleixandre, Rodríguez, & Duschl, 2000; Lizotte, McNeil, & Krajcik, 2004; Marttunen, 1994; Mason & Santi, 1994; Russell, 1983); prescriptively, it has been claimed that good arguments should contain Toulmin's various argumentation components (Chinn, 2006; Kenyon & Reiser, 2006; Knudson, 1994; Toth, Suthers, & Lesgold, 2002; Yeh, 1998). In the domain of writing, it has been used to encourage students to make their warrants more explicit and elaborate (Chambliss & Murphy, 2002; Rottenberg, 1988). Although explicitness is important, these efforts give short shrift to the consideration and integration of counterarguments (van Eemeren, Grootendorst, Jackson, & Jacobs, 1993; Willard, 1976). According to the Toulmin model, good arguments should contain a rebuttal to an implicit or briefly mentioned counterargument, but there is no emphasis on developing strong or multiple counterarguments.

Fortunately, more recent philosophic models of argumentation correct this problem. The pragma-dialectical school of argument (van Eemeren & Grootendorst, 1992) views arguments as constructed in dialectical exchanges known as *critical discussions*, the purpose of which is to resolve a difference of opinion in a rational manner. Another contemporary model of argumentation has been proposed by Douglas Walton (1995). In an analysis of a large selection of informal arguments, Walton (1996) identified different patterns of reasoning, which he called *argumentation schemes*. Associated with each pattern is a set of *critical questions* that a good reasoner should ask, such as "How strong is the likelihood that certain consequences will occur?" or "Are there consequences of the opposite value that should be taken into account?" Critical questions can also be found in the Toulmin model, but the Walton model contains a greater number and variety of critical questions, providing a stronger basis for pro- and contra-argumentation. Pro- and contra-argumentation in turn provides the basis for the theoretical concept explored in this article: argument-counterargument integration.

### *Argument-Counterargument Integration*

In the psychology of reasoning, an important consideration is how to make students' reasoning more balanced. Individuals often reason in biased ways, specifically by searching for evidence that supports prior beliefs and by ignoring counterevidence (Chinn & Brewer, 1998). Confirmation and belief biases are well documented in the literature on reasoning (Mayer, 1992). To overcome these biases, educators must teach students to reason in a balanced way, encouraging students to bracket and critique their biases (through asking critical questions) and to consider opposing views as much as their own views. For this reason, much attention has

been given in argumentation research to encouraging students to generate counterarguments (Kuhn, 2005; Nussbaum, 2005).

But it is important for students also to learn to critically evaluate arguments and counterarguments in order to reach an overall final conclusion. Nussbaum and Schraw (2007) termed this process *argument-counterargument integration*. Argument-counterargument integration is loosely based on neo-Piagetian views of reasoning development (Case, 1985; Halford & McCredde, 1998). This perspective views development as a process of coordinating and integrating disparate elements (in working memory) into a more coherent conceptual structure (McCutchen, 1996). In argumentation, the disparate elements are individual arguments and counterarguments that can then be integrated in various ways. Effective argumentation also involves metacognitive reflection, a "stepping back" that allows one to view and weigh the overall merits of different arguments and counterarguments (Kuhn, 1991, 2005), specifically by asking critical question (Walton, 1995). Argument-counterargument integration is also informed by (a) Suedfeld, Tetlock, and Streufert's (1992) work on measuring integrative complexity, which is the degree to which people make distinctions (*differentiation*) in discourse and conceptual connections among these distinctions (*integration*) and (b) the work of Leitão (2000), who examined replies to counterarguments in the context of everyday discourse and found examples of *integrative replies* that qualified original positions by acknowledging and integrating counterarguments.

### *Application to Writing*

Student writing assignments have long been viewed as a vehicle for promoting student learning and critical thinking (Knipper & Duggan, 2006; Pandis, Ward, & Matthews, 2005). Writing allows students to reflect on and draw linkages among ideas. Students also learn to formulate and critique written arguments.

*Persuasive versus reflective writing.* Most students are taught to formulate arguments during writing (if they are taught argumentation at all) in the context of *persuasive writing*. Students are frequently taught to develop a thesis and defend it by citing reasons and evidence in support of their position (Fulkerson, 1996). This is the basis of the infamous five-paragraph essay. Using less scripted techniques, educational researchers (e.g., De La Paz, 2005; Ferretti, MacArther, & Dowdy, 2000; Nussbaum & Kardash, 2005) have explored how to promote better writing among students of all ages by having them set goals and subgoals for their writing (for example, subgoals to provide reasons, evidence, explanation) and to engage in various self-regulatory activities to improve the persuasiveness of their essays (Graham, Harris, & Mason, 2005). Nevertheless, teaching persuasive writing tends to promote one-sided thinking. Students do not tend to consider counterarguments when writing persuasive essays (Santos & Santos, 1999; Stapleton, 2001), or they consider them only briefly.

Recently, there have been calls to teach students a different genre of argumentative writing, which I shall term *reflective writing* (see also Kim, Anderson, Nguyen-Jaheil, & Archodidou, 2007). Other names given to this different genre have included *deliberative writing* (Kroll, 2000), *analytic writing* (Nussbaum & Kardash, 2005), or *constructive argument* (Hewlett, 2006; Mallin

& Anderson, 2000). Reflective writing provides a context for argument-counterargument integration. The focus in reflective writing is on exploring and integrating various sides of an issue in order to reach a reasoned conclusion. In contrast to persuasive writing, in which the student starts with a conclusion and defends it, in reflective writing, the conclusion comes at the end (although it certainly can be summarized in the introduction). Reflective writing allows for a more in-depth exploration of a problem or question. It provides students with an opportunity to practice a greater variety of critical thinking operations.

*Collaborative argumentation.* Persuasive writing reflects an adversarial approach to argumentation in which one side attempts to win over another. Reflective writing, on the other hand, is more consistent with recent attention in argumentation research on collaborative reasoning (Anderson et al., 2001), which is said to promote a greater exploration of ideas (Keefer, Zeitz, & Resnick, 2000), more conceptual change (Chinn, 2006; Driver, Newton, & Osborne, 2000; Reznitskaya et al., 2001), and better problem-solving skills (Wegerif, Mercer, & Dawes, 1999). Much of this research has been conducted in the context of oral discussions, however, and not specifically in essay writing. Although essay writing is often an individual activity, it is still dialectical in the sense that the writer can pose questions to himself or herself and answer them, or otherwise have an internal dialogue (Vygotsky, 1978). Most philosophers now consider the construction of arguments an inherently dialectical activity (Freeman, 1992; Johnson, 2002), and from an educational psychology perspective, enhanced internal dialogue is related to better planning and self-regulation of the writing process (Harris, Graham, & Mason, 2006; Reznitskaya et al., 2001). Thus, the recent theoretical turn toward collaborative argumentation is also applicable to essay writing.

*Strategies for argument-counterargument integration.* How can the concept of argument-counterargument integration be applied to the writing of reflective essays? Nussbaum and Schraw (2007) identified several strategies that students can use to achieve argument-counterargument integration. First, in a weighing strategy, the arguer considers both sides and then considers which side has the stronger arguments (for example, Do advantages outweigh disadvantages?). Second, in a synthesis strategy, the arguer finds a final standpoint between different sides (e.g., finding a creative solution in which benefits are realized while disadvantages are minimized or in recognizing that the wisdom of an alternative may depend on certain factors; that is, it may be wise in some circumstances but not in others). The use of creative synthesis as an argumentation move is neglected in most current argumentation models (e.g., Toulmin, 1958; van Eemeren & Grootendorst, 1992), even though various educational psychologists have called for more attention to be given to creative thought (Bereiter & Scardamalia, 2006; Sternberg & Lubart, 1991).

A third strategy identified by Nussbaum and Schraw was *refutation*, showing that one or more arguments on a particular side of an issue are false, irrelevant, or insufficiently supported. Refutation is not a strong integration strategy because—while it addresses counterarguments—it tends to be associated with one-sided reasoning, rather than balanced reasoning. Nevertheless, refutation can be used in the context of balanced reasoning if used selectively (e.g., some arguments are refuted but others, on both sides, are weighed or synthesized).

### *Nussbaum & Schraw (2007) Study*

Most prior argumentation models have emphasized refutation over integration. As a result, there is a dearth of psychological research on how well individuals are able to integrate arguments and counterarguments. In an initial study, Nussbaum and Schraw (2007) asked 84 college undergraduates to write reflective essays on the topic, "Does watching TV cause children to become more violent?" The study had a  $2 \times 2$  factorial design, and two interventions were aimed at promoting argument-counterargument integration. The first was to briefly instruct students on the qualities of a good argument (i.e., arguments should have a clear position, adequate supporting reasons, compelling counterarguments with supporting reasons, and a final conclusion that reflects one of the argument-counterargument integration strategies). This instruction was provided in the context of an extended example, "Should Janet Jackson and Justine Timberlake be fined for the baring of Jackson's breast at the Superbowl?" The second intervention was to provide students with a graphic organizer to help plan their essays. The organizer consisted of several ovals for students to fill in: an argument oval (and ovals for supporting reasons), a counterargument oval (and ovals for supporting reasons), and an oval at the top for an overall final conclusion.

The researchers found that the integration strategies were enhanced when students were given instruction on the criteria of a good argument. On the other hand, use of a graphic organizer to plan essays only enhanced a refutation strategy. The organizer helped students manage working memory demands, making it easier for them to remember counterarguments and thus to rebut them.

It was not clear, however, why only refutation was enhanced. One possibility relates to how the graphic organizer was designed; the integration oval was placed at the top, showing that it was supported by the various arguments. Although students were instructed to complete the integration oval last, some may have completed it first, thus prematurely committing to a side. Another possibility was that students may have had more experience with the refutation strategy than the others (although data are needed to confirm this), so unless students were explicitly cued to use the other strategies, they tended not to do so. Furthermore, such cues may need to be integrated with the graphic organizer.

Alternatively, there may be something inherent about graphic organizers that facilitate refutation. Organizers make arguments-counterarguments salient, so it is easy to pick arguments to support and refute. The processes of weighing arguments, or constructing creative solutions, are harder to make visually salient. Furthermore, organizers invite students to think of several arguments on one side of an issue before those on the other side, and cognitive interference (from thoughts on one side) may make it harder to develop arguments on the other side as much, making it easier to refute. In the Nussbaum and Schraw (2007) study, students who received both interventions (criteria instruction and then the graphic organizer) still tended to use refutation over integration strategies, even though they received instruction in integration. An important question is whether the graphic organizer can be redesigned to facilitate integration strategies.

## The Present Study

The present study had three goals. First, given the failure of graphic organizers to promote integrative reasoning in the previous study, I sought to evaluate a longer term intervention in which students were given more help in understanding the purpose of the graphic organizer and more practice using it. This was done by redesigning the graphic organizer (described later), combining the organizer with more instruction specifically on how to integrate arguments and counterargument, and strengthening the instruction to include discussion of “critical questions” that should be asked when integration is performed. I hypothesized that the redesigned intervention would result in more balanced reasoning in the experimental group compared with that in a control group and that the effects would grow stronger over time.

The second goal was to understand the argumentation “moves” (or stratagems; Anderson et al., 2001) that individuals use when performing the integration task. This research question was open ended and intended to shed light on which moves participants naturally used (specifically, the moves by those in the control group) as well as those moves used after training. It was anticipated that some participants would use moves that were more normatively advanced than others. Identifying moves that participants found feasible to use can inform future training efforts. It was hypothesized that among participants who did engage in argument-counterargument integration, the most common strategy would be synthesis (developing creative solutions), because synthesis creates a more unified mental representation that poses lower cognitive load than weighing, which requires maintenance of a number of disparate elements in working memory. Weighing was anticipated to be the strategy used the least.

The final goal was to better understand participants’ instructional histories in regard to writing opinion essays. One explanation of the Nussbaum and Schraw (2007) finding of a tendency to use biased reasoning with graphic organizers was that biased reasoning was the default mode used, specifically because that is the type of persuasive reasoning typically taught in schools. However, no data were collected on participants’ instructional histories, so in the present study, a survey was included in this regard. It was hypothesized that some students would have had some prior training in refuting arguments but little or no training in other, more balanced integration strategies (i.e., weighing costs and benefits, or designing a creative solution).

## Method

### Participants

Participants were 45 undergraduates at a large, southwestern university recruited from educational psychology courses. Most were education majors (53% elementary, 18% secondary, and 14% other); the remaining were majoring in other disciplines (13%) or were undecided (2%). Almost all (89%) were seeking a teaching credential and were either juniors (56%) or sophomores (38%). The average grade point average was 3.16. The ethnicity breakdown was 66% European American, 16% Hispanic/Latino, 9% Asian/Asian American, 5% African American, and 4% other. In respect to gender, 84.4% were women, and 15.6% were men. Students participated in the experiment to meet a course requirement.

## Materials

**Writing prompts.** There were four writing prompts related to (a) requiring school uniforms, (b) accountability systems, (c) ability grouping, and (d) grading for effort or participation. Each prompt mentioned some arguments that students could use (pro and con), but gave no guidance on integration except for instructing students to write arguments on both sides and then develop and support their opinion. The complete prompts are contained in Appendix A. To randomize the order that the prompts were given to the participants, I randomly assigned each participant to one of four different prompt sequences; the participants received one prompt per session. The prompt orders were as follows:

Order 1: uniforms, accountability, grading, ability grouping.

Order 2: ability grouping, grading, accountability, uniforms.

Order 3: grading, uniforms, ability grouping, accountability.

Order 4: accountability, ability grouping, uniforms, grading.

**Graphic organizer (AVD).** Figure 1 shows the redesigned organizer. The form was called an *argumentation vee diagram* (AVD) and was adapted from a form originally used by Novak and Gowin (1984) to structure science investigations. Unlike the form used in Nussbaum and Schraw (2007), the integration section of the form in the present study was placed at the bottom, so that students would be less tempted to fill it out first. In addition, two critical questions were included on the form to cue various integration strategies: “Which side is stronger, and why?” and “Is there a compromise or creative solution?” Students could also use a refutation strategy by drawing an arrow between an argument and the counterargument that refuted it (or a rebuttal that refuted the counterargument) and were informed of this possible response both in the training and in the written instructions.

To determine whether placing one of the critical questions first made any difference, we developed a second version of the AVD form (i.e., Form B). With this form, the first critical question asked was, “Is there a compromise or creative solution?” followed by the question, “Which side is stronger, and why?” We randomly assigned students to use one of the two versions of the form and, as will be reported later, the version of the form that the students used had no discernable effect.

Figure 1. Argumentation vee diagram. The question is written in the vee. Arguments and counterarguments are paraphrased in the spaces outside the vee. A final conclusion and argument is written at the base of the vee.

*Training materials.* For training purposes, overheads (and handouts) of a completed AVD were prepared on a question related to whether the university should lease parking spaces to faculty and students (see Figure 2). A whiteboard was used to complete an AVD on the topic of whether watching TV causes children to become more violent, with a blank AVD projected onto the whiteboard.

*AVD evaluation form.* Students in the experimental group also completed a survey after using the AVDs regarding whether they perceived the AVDs as helpful and whether participants were given sufficient time to complete them. The evaluation, which consisted of six open-ended questions, is shown in Appendix B. It took about 3–4 min to complete.

*Prior experience or instruction with integration.* We administered an 18-item survey to assess the students' prior experience and instruction with the different integration strategies. Students rated, on a 4-point Likert scale, their prior experience with such things as discussing counterarguments or designing creative solutions. Appendix C lists the exact items. The survey took about 5 min to complete.

### Design and Procedure

This study was to some extent a design experiment (Brown, 1992; Design-Based Research Collective, 2003), in which small changes were made to the intervention in mid-course to improve its effectiveness. These changes will be described later. In addition,

a repeated measures design was used, with participants randomly assigned to either the experimental ( $n = 22$ ) or control group ( $n = 23$ ). Participants attended four 1-hr sessions; during each session, students wrote for 30 min on one of the four topics (the order was selected randomly for each student). The amount of remaining time was announced after 15 min and 25 min. I conducted all the sessions. During Session 1, the purpose of the study was explained, as follows:

This study examines opinion essays, where one examines both sides of an issue and then takes a stand. The purpose of the study is to examine how people write opinion essays and the effects of repeated practice. You will write one essay per session and may also receive some feedback and training.

Participants then completed informed consent forms and then the demographics survey. They were then told that they would have 30 min to write an essay; this essay served as a baseline measure. They were also told that everyone would be writing on a different topic. After removing their prompt from a manila envelope (which contained all their materials), they were given the following instructions:

Your essay should give reasons for and against each viewpoint and should then present and justify your viewpoint. Don't worry about spelling and grammar. You may spend a few minutes planning what you will write. If you complete your essay early, please sit quietly until everyone is done.

The procedures for the experimental and control groups were the same up to this point. The session for the control group was then concluded. The experimental group, on the other hand, was introduced to AVDs via a worked example on leasing university parking spaces (see Figure 2). The integration section of the example illustrated both a weighing and a synthesis strategy. An overhead projector was used to show students examples of both the blank and completed AVDs shown in Figures 1 and 2. Then, participants were asked as a group to give arguments on the other training topic (whether TV causes violence) and—as a group—constructed a completed AVD on the whiteboard.

During Session 2, the parking AVD was reviewed with the experimental group; they received copies of both a blank AVD and a completed one. Experimental group students were asked to individually complete a practice AVD on TV violence. They were also reminded that it was not necessary to answer both integration questions listed on the AVD, just one or the other. Participants were then given 8 min to complete an AVD on their writing topic for that week and 30 min to prepare their essay. The period of 8 min was judged as sufficient on the basis of a pilot session, but a question on this issue was asked on the AVD evaluation surveys, which were completed at the end of the session by the experimental group.

During Session 3, students received written feedback on the two AVDs that they had prepared the previous week. Also, the weighing strategy was discussed in more detail; students were asked, in the context of the TV violence training question, "What sort of things generally make one side stronger than another?" The list generated from the question was discussed. I then mentioned that *prevalence* (the extent of an advantage or disadvantage) and *value* (the importance of a specific advantage or disadvantage) should be relevant considerations, along with evidence. I also told the stu-

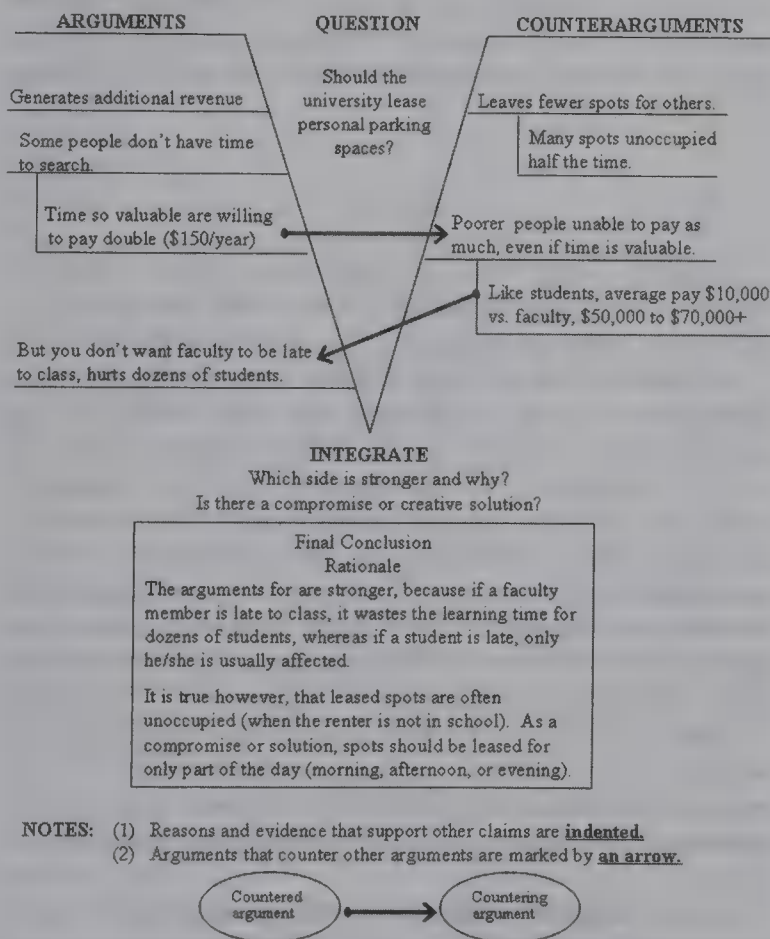

Figure 2. Completed argumentation vee diagram on the question, "Should the university lease personal parking spaces to faculty and students?"

dents that the arguments did not have to be completely pro or con to be put on the AVD but that they had to decide on which side each argument would best fit. Students then prepared their essays, planning them with the AVDs as before. They also completed the prior instruction/feedback survey and another AVD evaluation form.

The fourth session was used to assess internalization and transfer of the integration strategies; students wrote on a new topic based on the prompt assigned to them that week, but they were not provided with AVDs. They were given 8 min to plan their essay.

Unlike the experimental group, the control group participants were not given any instruction in argument-counterargument integration or in essay writing. As with the experimental group, the control group was told that the purpose of the study was to see whether the quality of their arguments improved with practice. Like the experimental group, they were given 8 min of planning time before writing each essay but were not provided with AVDs. They were instructed—both orally and as part of their writing prompts—to address both sides of an issue and then to take a stand, giving their opinion along with supporting reasons.

The control group did not complete the prior experience and instruction form as this could have cued them to use integration strategies. One goal of the study was to examine what strategies students naturally use.

### Coding

Each essay was coded for the presence of one of the three integration strategies: specifically weighing (contrasting the relative merits of an argument or counterargument), synthesis, and refutation. Each category was coded dichotomously, indicating the presence or absence of that strategy. The coding system allowed for the possibility that a student could use more than one strategy. After I had performed some preliminary coding, it became clear that an additional category called *pseudo-integration* was needed. In pseudo-integration, students indicated that the case for a particular side was strongest but supported their assertion simply by picking a supporting argument they liked best. This is not true integration, because the integration ignores how to address counterarguments. The pseudo-integration category was subdivided into either just restating, at the end of an essay, the strongest argument versus adding onto the argument (*amplifying*) to make it stronger (e.g., adding examples and explanations, or explaining why a consequence is important). Students who used one of the three strategies (synthesis, weighing, or refutation) received a 0 for pseudo-integration, since it was conceptualized as an alternative to integration.

Appendix D contains excerpts from essays reflecting the different coding categories. Brief summaries of the examples are given below. All scoring was performed blind to condition and session.

**Synthesis.** Synthesis was indicated by either (a) a claim describing how an alternative should be designed to alleviate negative consequences (e.g., “Accountability systems should use multiple types of assessment, so the curriculum will not be overly narrow”), or (b) contingent claims (e.g., “It depends”) that specify the conditions under which the arguments apply and the conditions under which the counterarguments apply (e.g., “Whether ability grouping is a good educational practice would depend on whether students can move up to a higher group”).

**Weighing.** A weighing strategy was indicated by either (a) an argument that a value associated with one side is more important than a value on the other side (e.g., “In grading, rewarding effort is more important than measuring K–12 content knowledge because, in the long run, it is effort that will lead to career success”), (b) an argument that a certain advantage is more prevalent than a disadvantage or vice versa or that a certain advantage or disadvantage is not all that widespread (e.g., on the school uniforms topic: “Conflicts related to clothing are infrequent”), or (c) an argument that an advantage on one side could be realized by the other side (e.g., “In grading, class participation promotes learning as much as just assessing knowledge because students are learning social skills”).

**Refutation.** In refutation, the writer makes an argument for why a counterargument is weak or flawed (e.g., in writing on the school uniforms topic, a writer refutes the counterargument that freedom of expression is suppressed by noting that students can express their persona in other ways, such as through hair style). Refutation removes the “force” of the counterargument by showing that it not that applicable or likely or that it rests on a faulty assumption.

**Pseudo-integration.** In pseudo-integration, a writer presents both sides of an issue and then (typically in the final paragraph) indicates which side he or she agrees with and why. However, no reference to the arguments on the other side is made. The writer just restates or amplifies arguments made on the favored side (see Appendix D for examples).

**Interrater reliability.** All essays were independently scored by two raters: the researcher and a graduate assistant who was unaware of the study’s hypotheses. All disagreements were resolved through discussion. Interrater agreement for all scoring categories was 80% or higher.

### Results

Frequency counts of the strategies used are shown in Table 1. There were five cases of students who used more than one strategy in an essay; these are indicated in the footnotes to the table.

For purposes of the statistical analysis, scores for synthesis were aggregated with those for weighing and called *integration*. Because the critical questions on the AVDs prompted students for these two strategies, it was hypothesized that overall integration associated with these strategies would increase. This hypothesis did not differentiate between the two strategies (the use of one or both could increase), so to test the hypothesis, I combined scores from the two categories. (There was a separate hypothesis that synthesis would be used more than comparison by both groups, but this conjecture was not tied to the treatment and so will be discussed later.) The use of the term *integration* for synthesis and weighing is not meant to imply that refutation does not also involve some form of integration, but it is a weak form (counterarguments are acknowledged and evaluated, but ultimately rejected).

Because almost all variables were dichotomous, logistic regression was used to analyze the results. Logistic regression is more valid than analysis of variance (ANOVA) when the outcome variable is dichotomous because of nonnormality and nonuniform variances; also, linear methods assume the outcome variable can

keep increasing beyond the value of 1 and so are misspecified (Agresti, 2002).

The integration variable in this study ranged from 0 to 2; however, a 2 was assigned in only three cases. Because the presence of 2 was so infrequent, I simplified the analysis by making the variable dichotomous (replacing the 2 with a 1), so that the variable merely reflected the presence or absence of integration.

The lack of independence among observations from the same person was controlled with hierarchical linear modeling (HLM) and MLwiN statistical software (Rabash, Steele, Browne, & Prosser, 2005); Time was used as Level 1 and Participant as Level 2 (i.e., Time was nested in Participant). HLM is increasingly being used to analyze time series data (Tan, 2008) and can be applied to binary outcomes (Rabash et al., 2005).

### Results of Intervention

We first consider the results of the first three sessions, because the fourth session was a transfer session in which no AVDs were used. Only data for the 42 participants who attended all three sessions were used. There was not a significant difference in the frequency of the prompt orders between the two conditions,  $\chi^2(3, N = 42) = 0.98, p = .81$ , indicating the attempt to balance the prompt orders was successful.

As shown in Figure 3 and Table 2, the effects of the intervention over time were positive. With use of integration strategies as the dependent measure, there was a Time (Session)  $\times$  Condition interaction,  $B = 1.31, p < .01$ , odds ratio (OR) = 3.71, with a significant difference between the experimental and control groups for the third session favoring the experimental group,  $\chi^2(1, N = 38) = 4.68, p < .05$ , Cramer's  $V = .38$ . Specifically, 67% of the essays in the experimental group were integrated, while only 29% of the control essays were. There was not a significant Time  $\times$  Treatment interaction for refutations,  $B = -2.29, p = ns$ , OR = .10, or pseudo-integration,  $B = -0.03, p = ns$ , OR = 0.97.

These effects did not occur during the transfer session (Session 4), when the AVDs were not used. There was no significant difference for integration,  $\chi^2(1, N = 42) = 0.02, p = ns$ , Cramer's  $V = .02$ .

There was no evidence that the amount of integration on the AVD-planned essays was affected by the order of the integration questions (putting "Which side is stronger, and why?" vs. "Is there a compromise or creative solution?" first). Half the participants ( $n = 11$ ) received one type of AVD, and the other half ( $n = 11$ ) received the AVD with the question order switched. Participants who received one type of AVD during Session 2 received the other type during Session 3. Results of Mann-Whitney exact tests showed the order of questions had no statistical effect within the experimental group on integration during either Session 2 ( $U = 57.5, p = .85$ ) or Session 3 ( $U = 50.0, p = .76$ ).

### Nature of Integration Strategies

In order to better understand the nature of the integration strategies that were used, I conducted further analysis by subtype. Integration strategies can involve synthesizing a creative solution or weighing (i.e., weighing advantages against disadvantages).

Table 3 presents the means and standard deviations of the strategies used. Table 4 presents the counts of the different integration strategies aggregated over the four sessions, along with the proportion that each strategy was used. The total figures show that about one half of the students engaged in either no integration (27.4%) or pseudo-integration (25.1%). Of those who engaged in integration, synthesis (e.g., finding a creative solution) was the most common strategy (26.9%), as expected. Synthesis possibly creates an integrated representation that places a lower burden on

Figure 3. Mean use of integration strategies, comparing experimental (Exp., diamonds) and control (squares) groups for Sessions 1–3 (A) and for the transfer session, in which no AVDs were used by the experimental group (B).

working memory than do the other strategies. As expected, weighing was uncommon (10.3%) but was tied with refutations (10.3%). Because a prior hypothesis was made about the relative frequency of synthesis versus weighing, the difference was subjected to a statistical test and found to be significant,  $\chi^2(1, N = 42) = 12.94$ ,  $p \leq .001$ .

Because these figures could have been affected by the intervention, I also examined figures for just the control group, and a similar picture still emerged. Synthesis and pseudo-integration were again the most frequently used strategies (26.4% and 19.5%, respectively). With pseudo-integration, it was common for students to pick what they considered to be the strongest argument and to elaborate on it further (providing additional reasons, examples, or explanation of importance), a process that has been termed *amplification* (see Perelman & Olbrechts-Tyteca, 1958/1969). Amplification occurred 43% more often compared with just re-statement of the strongest argument. In the control group, the least

used strategy was weighing,  $\chi^2(1, N = 21) = 9.97$ ,  $p \leq .002$ , compared with synthesis.

Although students rarely used weighing strategies, this does not mean that such strategies are unimportant; these strategies can be quite effective in identifying the best course of action, as implied by classical decision theory (Baron, 1988). Nevertheless, such strategies must also be psychologically realistic, meaning that they can be used by individuals with some amount of ease. Analysis of how participants actually used weighing strategies in this experiment can shed light on this issue. Weighing was not comprehensive; that is, students—at least explicitly—did not consider the total weight of arguments on one side and balance them against those on the other. Instead, they reasoned more locally, where just one argument was contrasted with another on the other side. (The strategy would be considered a heuristic shortcut, which facilitates judgment while minimizing cognitive demands; see Goldstein & Gigerenzer, 2002.) In the total corpus, weighing strategies were used 18 times. In 53% of these cases, students mentioned two arguments (on different sides of an issue) and indicated that one argument reflected a more important value. In another 10% of the cases, the students made an argument that a value was realized on both sides of an issue. In the remaining 38% of cases, the students argued that a particular disadvantage was not that widespread or important (for example, “Children’s free expression is not that important; school is about fitting in”) and contrasting it with another value (for example, “avoiding being teased about wearing cheap clothes”), a process that was termed *minimization* (in contrast to amplification). This was not an integration strategy that had been anticipated; however, we did discuss problem prevalence during Session 3 (and 83% of the minimization cases occurred in the experimental group during or after Session 3). I therefore tested whether, in the experimental group, there

Table 2

was a statistically significant trend for minimization to occur more frequently in the latter sessions; the test was significant ( $\tau = 0.22, p \leq .01$ ). This is evidence that use of this stratagem may have been affected by the instruction.

### Prior Experience and Instruction

Table 5 shows the means and standard deviations for the prior experience and instruction survey items. The table shows that participants had a moderate amount of experience (*M*s close to 2.0) in discussing and rebutting counterarguments and in writing persuasive essays that did not discuss counterarguments or that discussed them only briefly. Thus, as expected, writing persuasive essays was a familiar writing genre for these students. However, so was writing essays in which two or more sides of an issue were explored in a balanced manner ( $M = 1.78$ ) and in which arguments and counterarguments were weighed ( $M = 1.83$ ). So participants

may have had some experience in reflective writing. However, the finding that they had experience weighing arguments against counterarguments was surprising because participants did not generally use explicit weighing strategies when writing their essays. However, pseudo-integration (just picking the argument that seems strongest and elaborating on it) was used the most frequently, and participants may have interpreted weighing in this fashion. It is interesting they had the least amount of experience and instruction with the two synthesis strategies (designing creative solutions or compromises between two sides), with means of 1.39 and 1.22, respectively, for experience and means of 1.22 and 1.33, respectively, for instruction. These figures reflect the response indicating *a little* experience/instruction (1.0) in synthesis and were statistically different from the response indicating *moderate* experience/instruction (2.0) on the basis of one-sample *t* tests,  $t(17) = -2.83$  for experience in creative design,  $t(17) = -4.08$  for instruction in creative design,  $t(17) = -3.76$  for experience in developing compromises,  $t(17) = -3.37$  for instruction in developing compromises,  $p \leq .01$  for all tests. Thus, the hypothesis that participants had little experience with and instruction in integration strategies was for the most part verified, particularly in relationship to synthesis.

### Participant Evaluations of AVDs

Although all participants in the experimental group were asked to fill out the AVD evaluation form, a few failed to do so because of time constraints. Usable responses were  $n = 21$  for Session 2 and  $n = 19$  for Session 3.

In response to Item 1, 95% of the participants indicated that they were given sufficient time to complete their AVDs during Session 2, but this figure dropped to 68% during Session 3 (percentage giving an unqualified "yes"). The remainder desired a few more minutes to think about the integration, but some noted that they were allowed to use some of the 30 min devoted to essay writing to complete their AVD. The decrease, which was statistically significant ( $p < .05$ , Fisher's exact test), may indicate that participants were responding to the weighing criterion that was introduced during Session 3; one participant noted that "we had more things to think about."

Table 4

Designing a compromise between two sides.	1.22	0.88	1.33	0.84
How much experience have you had in writing opinion essays?	2.11	0.76	—	—
How much instruction have you had in writing opinion essays?	—	—	1.89	0.76

*Note.* *N* = 18 (given to experimental group only). Response options: *None* = 0, *a little* = 1, *moderate* = 2, and *a lot* = 3.  
<sup>a</sup> Stem: “Before this study, please rate how much experience you have had doing each of the following while writing opinion essays.” <sup>b</sup> Stem: “Before this study, please rate how much instruction you have received regarding each of the following in relationship to writing opinion essays.”

All participants indicated that they were given sufficient time to prepare their essays (Item 2). In regards to Item 3, most thought—without qualification—that the oral and written directions for how to complete the AVDs were clear (78% for Session 2, 80% for Session 3). The remainder had various minor questions that were answered, at least for Session 2, during the following session; there was no common theme to any of these questions.

Item 4 asked what participants found beneficial about using argumentation vee diagrams. The responses were grouped inductively into categories; results are shown in Table 6. The dominant response was that the AVDs assisted students in organizing their essays. A few participants were more specific and indicated that the AVDs helped them “separate the two sides” or “keep track of which counterarguments cancelled out which arguments.” On the remaining evaluation items, no participant made any points repeated by other participants, so no themes were identified.

Discussion

This article presents argument–counterargument integration as a worthwhile task for students to engage in when writing reflective opinion essays. The study found that graphic organizers (argumentation vee diagrams) and instruction in strategies for integrating

arguments and counterarguments may have initially promoted only pseudo-integration, where students, in concluding their essays, picked one side of the issue and a supporting argument that they felt was strongest. This was not true integration because counterarguments, although previously stated, were then ignored. True integration, however, did emerge over time, with additional practice and instruction. The effect disappeared when support from the argumentation vee diagrams was withdrawn. Future research is needed to determine whether transfer effects can be obtained with a longer (e.g., semester-long) intervention. It is encouraging that there was still more pseudo-integration in the experimental group than in the control group during the transfer session, as this might signal the beginnings of some independent skill acquisition.

The hypothesis that writing reflective (rather than persuasive) essays would be a new genre of writing for these students was not confirmed; they reported some experience writing essays exploring two sides of an issue and even weighing advantages and disadvantages. However, an ability to explicitly explain why one side of an issue was stronger than another was not apparent in most student essays, so it is likely that such weighing just reflects pseudo-integration. In addition, students reported that they had received very little instruction in writing essays that propose compromises or creative solutions between two sides or instruction in how to develop refutations. Therefore, it appears that students could benefit from specific instruction in argument–counterargument integration.

In what follows, I first discuss specific conclusions relating to how this instruction should be designed. I then discuss more general issues regarding the theoretical and practical significance of the findings.

Design Issues

*Strength standards.* This study was to some extent a design experiment (Brown, 1992; Design-Based Research Collective, 2003), in which small changes were made to the intervention mid-course to improve its effectiveness. Specifically, after the first session, it was clear that students needed more instruction in standards of what makes one argument stronger than another, so

Table 6  
*Participant Comments on Benefits of Argumentation Vee Diagrams*

Category	Percentage	
	Session 2 <sup>a</sup>	Session 3 <sup>b</sup>
Assists with organization	36.4	73.7
Assists with brainstorming	13.6	15.8
Assists with time management	9.1	0.0
Helps in remembering and “seeing” thoughts	22.7	10.6
Helps in separating/correcting the sides	18.2	5.3
Helps in seeing which side is stronger	4.5	10.6
Unclear response	9.1	5.3

<sup>a</sup> *n* = 21. <sup>b</sup> *n* = 19.

they could avoid pseudo-integration. Because most of the discussion questions involved practical reasoning—that is, deciding among different courses of action (Walton, 1990)—classical decision theory was used as a guide.

According to classical decision theory (von Neumann & Morgenstern, 1944), individuals should choose the alternative that maximizes the expected utility for either themselves (according to classical economic models, Smith, 1980) or the community at large (according to social utilitarian models, Bentham, 1879/2000). Expected utility is a product of both the likelihood that various positive and negative consequences will occur from a particular course of action and the value attached to those consequences. Although there are strong debates in psychology as to what extent individuals can reason probabilistically (Anderson, 1990; Griffiths & Tenenbaum, 2006; Tversky & Kahneman, 1983), individuals can likely make qualitative judgments as to whether particular consequences are likely or unlikely, as well as valuable or less valuable (Grennan, 1997). Therefore, students were instructed to consider the prevalence and importance of particular consequences. Prevalence refers to how widespread a particular consequence would be (i.e., frequency); it is an easier way psychologically for individuals to think about probabilities (Goldstein & Gigerenzer, 2002).

*Graphic organizer design.* The graphic organizer used in this study was a redesign of one tested in a previous study (Nussbaum & Schraw, 2007) that found that the organizer resulted in more refutational (but not integrative) reasoning. That was not the case with the present study, indicating that the changes made to the graphic organizer (moving the integration section to the bottom of the form and adding integrative questions) were effective in improving the design. Nevertheless, the instruction that was provided to students could also have accounted for this effect. The focus in design research, however, is to design the strongest intervention possible, on the assumption that multiple components are necessary (interactively) to produce an effective intervention (Design-Based Research Collective, 2003). Additional cycles of redesign and implementation will be needed, however, to determine which aspects of the intervention are the most critical in producing integrative reasoning. It seems likely that AVDs used in the absence of any accompanying instruction would produce only pseudo-integration, given the prevalence of pseudo-integration in this study even in the experimental condition.

### Theoretical Significance

This section situates the theoretical significance of the findings in both philosophic and psychological models of argumentation.

*Philosophic models.* As noted in the introduction, Walton (1996) identified 22 patterns of reasoning, which he called *argumentation schemes*. Associated with each pattern is a set of *critical questions* that a good reasoner should ask. For example, one common scheme, and the one most applicable to the reasoning questions asked in this study, is *argument from consequences*, in which a course of action is supported by citing good consequences that will result from it or is rejected because of the bad consequences. Associated with *arguing from consequences* are three critical questions, specifically (from Walton, 1996, pp. 76–77): (a) “How strong is the likelihood that these cited consequences will occur?” (b) “What evidence supports the claim that the conse-

quences will occur?” and (c) “Are there consequences of the opposite value that should be taken into account?”

Walton’s critical questions provide some criteria for evaluating arguments (Nussbaum, 2007). Arguments that answer these questions are considered stronger because they take more considerations into account. The research reported in this article is most consistent with the Walton model but extends the model in that two additional critical questions are posed. The first is, “Can a creative solution be designed to realize the advantages of one side while minimizing the disadvantages of the other?” A number of educational psychologists have called for more attention to be paid to design thinking (Bereiter & Scardamalia, 2006; Sternberg & Lubart, 1991); these authors, as well as the results of this study, have suggested that it is rarely taught in schools. Another critical question suggested by the present study is, “How prevalent are the consequences of a particular course of action?” (lack of prevalence is the strategy of minimization). This is really a restatement of Walton’s first critical question but one that may be easier for students to master because it is one that was actually used by several reasoners in this study.

The Walton model, as amended here, may be a useful thing to teach to students. Specifically, students can learn to evaluate arguments by learning the key, critical questions that they should ask for different patterns of reasoning. Although many teachers attempt to teach critical thinking and critical writing, they lack well-defined instructional models of what factors constitute these skills (Paul, Elder, & Bartell, 1997). The framework elaborated in this article can provide the basis of critical writing instruction based in argumentation.

*Psychological models.* The initial theoretical basis of this study was neo-Piagetian theory, which contends that the development of reasoning consists of the coordination and integration of disparate elements in working memory (Case, 1985; Halford & McCredde, 1998). The development of functional working memory capacity and the creation of central conceptual structures (Case, 1992) have explained developmental phenomena in mathematics, literacy, and social and spatial reasoning (Case & Okamoto, 1996). In addition, knowledge integration has been proposed as a central goal of scientific reasoning (Linn & Hsi, 2000). So it seemed sensible to propose the integration of arguments and counterarguments as a worthwhile goal as well. Nevertheless, as this study proceeded, it became clear that students needed criteria with which to judge the strength of arguments.

In this study, Walton’s philosophic model became the basis of these criteria, suggesting that schema theory may be a useful supplement to the idea of argument-counterargument integration. Walton’s schemes are also psychological schemata that can be inculcated in students. The schemata have slots for different components of arguments (e.g., arguments, counterarguments, rebuttals) but also critical questions that should be asked about different components (essentially psychological operations associated with different slots). These schemata must be developed in students as a goal of instruction and can function as integrating devices.

While more research is needed to support this account, it is consistent with the work of Anderson and colleagues (Reznitskaya & Anderson, 2002), who identified a number of argumentation moves, called *stratagem*, that were used by students with increasing frequency in literature discussions (Anderson et al., 2001). Reznitskaya and Anderson (2002) claimed that stratagems are the

building blocks of argumentation schemata, which they used to explain transfer effects from oral discussion to writing. Stratagems are the psychological (and social) operations associated with different schemata. The present study is theoretically significant in identifying specific stratagem, such as minimization, that can usefully be taught to students, specifically as critical questions. Students can learn to ask themselves how widespread certain benefits or harms are or whether a creative solution can be designed to mitigate those harms. The present study shows that the concept of argument-counterargument integration likely needs to be supplemented with notions of schema in order to be theoretically and pedagogically powerful.

### Conclusion

As noted previously, much work on argumentation in education is based on the Toulmin model. Although this has yielded some informative research studies, it may have also constrained theoretical development in the field of argumentation research somewhat (Nussbaum, 2007). Use of alternative frameworks, such as those provided by argument-counterargument integration and schema theory, can provide new theoretical insights. The purpose of this research was to begin to develop (empirically and theoretically) an alternative framework. A corresponding limitation is that the framework is in an early stage of development and so needs more elaboration. Another limitation of this research is that the sample size for the survey on prior instruction was small, and so future research studies should seek to replicate these findings on a larger sample.

Future studies should also be conducted over a longer time frame. In this study, the progress made by students in the experimental group was not maintained when the AVDs were not used in Session 4. Longer term studies are therefore needed to determine how much instructional time is required for the argumentation schemas reflected in the AVDs to be internalized by learners and used spontaneously. Longer term studies should also identify whether students can be explicitly taught a minimization strategy. That was a useful argumentation stratagem that occurred in the study, but students were not taught it explicitly and it was not used on a wide scale. Finally, future research studies might attempt to disentangle the relative contributions of the graphic organizer from the verbal explanation, examples, and feedback that were provided with it. The effect of providing students with feedback on the extent and quality of their integration (but without their using AVDs) should also be explored.

A final limitation of the study was that prior to scoring, I did read the AVDs of the experimental group for Session 2 for the purpose of providing feedback, and although this was done several weeks before scoring, it is possible that some memory of these arguments may have provided cues as to which essays were in the experimental group, possibly biasing the scoring. It should be noted that no significant difference between the experimental and control groups was found for Session 2, however, so any unintentional biasing would have made no substantive difference in the results.

This study shows that complex critical thinking can be taught to students. A focus on key critical questions that students should ask themselves during writing, while integrating various sides of an issue, can help build the necessary schemata to promote more

reflective writing and ultimately, we hope, better decision making. Effective decision making is the cornerstone of successful democratic governance, and as the opening quote to this article on the Iraq war illustrates, it can also often be a matter of life and death.

## Appendix A

### Writing Prompts

#### Accountability

The Federal government mandates that every state have an accountability system by which schools are held accountable for how their students perform. For example, schools may be given greater or fewer funds on the basis of overall student performance on standardized tests. Also, some students in “underperforming” schools may be allowed to transfer. Advocates argue that accountability systems give schools an incentive to improve, may encourage or require more services and options to be provided to at-risk students, and provide parents and policy makers with information on year-to-year growth. Critics argue that accountability systems tend to narrow the curriculum, may punish schools that need the most help (in cases where funding is reduced), and may use indicators that are not totally valid.

In your opinion, should states be required to have an accountability system by which schools are held accountable for their students’ performance?

#### School Uniforms

Some people argue that public school students should be required to wear uniforms to school. Mandatory school uniform proponents argue that clothing is often a source of conflict in school, perhaps inciting theft and gang violence and also maintaining or widening the gap between those who can afford more expensive wardrobes and those who cannot. Requiring students to wear uniforms, they argue, not only removes this source of conflict but engenders a healthy attitude toward authority and

may make students take their education more seriously. Opponents of mandatory school uniform policies argue that school uniforms do not effectively deal with socioeconomic or cultural conflicts associated with clothing and that uniform policies discourage individuality and suppress freedom of expression.

In your opinion, should students in public schools be required to wear school uniforms? Think of as many reasons as you can on both sides of the issue when developing your opinion.

#### Ability Grouping

A third-grade teacher, Mr. Garcia, is planning to group his students into three reading groups (i.e., high reading ability, moderate reading ability, and low reading ability) on the basis of the results of a standardized reading test given to the students at the end of second grade. Is this good educational practice? Advocates of same-level ability grouping argue that it allows teachers to use materials and go at a pace appropriate for each student. Opponents of same-level ability grouping claim that it prevents the better students from acting as models for the weaker students.

What do you think? Think of as many reasons as you can on both sides of the issue when developing your opinion.

#### Grading

Is it good educational practice to base a portion of a student’s grade on such things as class participation, effort, or completion of

homework? Advocates of this practice claim that doing so gives students an incentive to try. Opponents argue that grades should only reflect how much a student has learned.

What do you think? Think of as many reasons as you can on both sides of the issue when developing your opinion.

### Additional Text

[Added to the end of each prompt was the following:] You will have 30 min to write an essay that discusses the issue and presents your opinion. (Do not worry about spelling and grammar.)

## Appendix B

### AVD Evaluation Form

Please answer each of the following questions regarding your experience today using an argumentation vee diagram (AVD).

1. Were you given sufficient time to complete the argumentation vee diagram? If not, please explain.

2. Were you given sufficient time to write your essay? If not, please explain.

3. Were the oral and written directions of how to complete an argumentation vee diagram clear? Are there any specific portions that you feel need more explanation? Please be as

specific as possible in regards to what you don't understand, if anything.

4. What do you find beneficial about using argumentation vee diagrams?

5. Is there anything you found unhelpful about using argumentation vee diagrams?

6. Do you have any specific suggestions about how we might improve the diagram or the procedure for using them? (You may write on the reverse side of this form.)

## Appendix C

### Experience and Instruction Survey Items

[The survey items were scored on a 4-point Likert scale, with response options: *none*, *a little*, *moderate*, and *a lot*.]

1. Before this study, please rate how much experience you have doing each of the following while writing opinion essays:

a. Discussing counterarguments (reasons others might disagree with you).

b. Rebutting counterarguments (reasons the counterarguments are wrong).

c. Weighing arguments and counterarguments (to decide which side is stronger).

d. Designing solutions that address both arguments and counterarguments.

e. Writing an essay designed to persuade others of a point of view but which does not discuss counterarguments?

f. Writing an essay designed to persuade others of a point of view and which briefly discusses counterarguments.

g. Writing an essay that explores two or more sides of an issue in a balanced manner (with about the same amount of discussion of each side).

h. Designing a compromise between two sides.

i. How much experience have you had in writing opinion essays?

2. Before this study, please rate how much *instruction* you have received regarding each of the following in relationship to writing opinion essays: [same items as in Question 1, except Item E was as follows: How much instruction have you previously received in writing opinion essays?]

## Appendix D

### Coding Examples

Below are more complete examples of each coding category, excerpted from the essays analyzed in the study. Author's comments are in brackets.

#### Integration Strategies

##### Synthesis

*Creative solution.* Concluding paragraph: I feel that states should have an accountability system to measure educational performance, but not have it be just off standardized test. Testing is not the best way to measure individual learning. Along with

testing, schools should consider how many students participate in extracurricular activities that the school offers. Like sports and clubs. They should also view classroom participation and social interactions. Schools need to be a catalyst for making the students better overall people in society. Some students may not test well, or the test may have biases. Testing is a good form to get an idea of a group's knowledge, but when looking at a school's overall performance, you must look at other factors as well. It's important to see how the school is involved and intertwined within the community. (Participant 15)

*Contingent ("It depends").* I feel that ability grouping is an excellent idea. It's good educational practice for the students as well as for the teachers. I also feel that it all depends on how the teachers want to organize and structure the ability group, so that the students would not get bored or feel uncomfortable about their reading skills. I also feel that the students should feel some type of achievement of their reading skills in knowing that they can improve and move on to the next reading level. The teacher should make the students feel engaged with their reading groups as well as feel and be engaged to improve their reading skills. (Participant 13)

### *Weighing*

*One value more important than another.* [In discussing whether students should be graded on class participation, effort, and completion of homework, the participant argues that effort is more important than knowledge]. . . Is it fair that my peers get the same grade as I do without "the effort?" I think the real question here is, what is the goal of education? If learning the facts is the main goal, then yes, it is fair that we get the same grade for acquiring the same amount of knowledge. Does our grade indicate our success in the future? I think not. I believe that my hard work and dedication will pay off in the end and that eventually the grades I got won't matter.

If the goal of education is simply to teach for the purpose of knowledge than the rest is not important. But if the purpose of education is to have successful professionals in society than yes, it is very important to give credit where credit is deserved. Some of us may not be math geniuses, but we try as hard as we can and hope that it is enough. If educators put more emphasis on effort, then the knowledge will eventually come. (Participant 23)

*Minimization.* [In comparing alternatives, a minimizing argument is one that shows that the advantages or disadvantages of one course of action will be limited.]

Clothing, I believe, has some to do with conflicts in school. Students group themselves with others who act, dress, and speak similarly to themselves. Clothing may blur the lines of different socioeconomic status, but only for a brief moment [minimizes the extent of the benefit]. Therefore, uniforms may not change much. Uniforms may, however, help students focus more in class by getting rid of distractions. Distractions such as logos and proper fit might influence some students. Uniforms could also create a more professional and conservative atmosphere for students to grow up in. I think that school uniforms is a good idea, but I don't think it is such a detrimental aspect to the students' educational success [minimizes the harm of clothing]. It is possible that uniforms could suppress student individuality and influence student rebellion, but not to an extreme [minimizes harm]. Mandatory school uniforms in public schools is a good idea but not a necessity. (Participant 46)

### *Refutation*

Even though students are prohibited the freedom to wear what they choose and maybe suppressed to "express" their speech through dress style, they are still able to express themselves based on how they carry out their persona. Their personal dress style may still be shown on how a student wears their hair, make up, and shoes. By no means is individuality being suppressed because their

uniqueness is greater seen through their actions rather than dress styles. (Participant 12)

## *Pseudo-Integration*

### *Restatement*

[At the conclusion, the writer picks one side and justifies it by restating arguments that were already made. In the following example, paragraphs are numbered for ease of reference.]

1. Should teachers and schools be held accountable by the Federal government for "underperforming" students in schools? Advocates argue that this accountability system gives schools incentives to improve. They also argue that it provides struggling students with more services. Critics argue that this accountability system narrows the curriculum and punishes schools that need the most help. Teachers and schools should not be held accountable for these underperforming schools due to the negative effects that they have on the students.

2. Advocates for accountability systems believe that the system will cause schools to improve. If a school is underperforming, the government cuts funds to the school to make the school want to improve. This is the opposite of what the government should do. The government should give more money to the "at-risk" schools, and spend more time training and preparing the teachers at the underperforming school rather than firing them. Advocates also argue that the system keeps the public up-to-date on how every school is doing. If a school does bad one year, then parents will pull their kids out of that school and will put them in a "smart" school, which will also cause many problems.

3. Accountability systems cause a narrowing of the curriculum at many schools. Many schools cut subjects such as science and social studies to focus more on language arts and math which is on the test. This limits the teacher on teaching to their full capability and it limits the students on crucial knowledge that they need in the future. Schools that narrow the curriculum have teachers that "teach to the tests." Teachers only teach what they know will be on the test, and that is not fair for the students.

4. Accountability systems should not shut down underperforming schools. The government should get help for these schools and provide them with the things that they need to help them improve in the future. Shutting down schools hurts a community, and mostly the students in the schools. Students who failed at an underperforming school will most likely fail at an adequate school also. In this situation, no one wins.

5. [All ideas in this concluding paragraph were made before. The opposing side is ignored.] Teachers and schools should not have accountability systems. These systems limit teachers, administrators, and many students [summary of Paragraph 3]. "Underperforming" schools should receive help from the government, not punishment [summary of Paragraph 4]. Teachers should not have to narrow their curriculum just so their students can pass the standardized tests [point made in Paragraph 3]. Accountability systems are narrowing the future of many struggling schools and students in America. (Participant 37)

### *Amplification*

[In this category, the writer, in the conclusion, picks one of the sides and elaborates on at least one of the supporting arguments to

make it more compelling and convincing. In the following example, the amplifications in the concluding paragraph are shown in italics.]

Some believe that a portion of a student's overall grade should account class participation effort and/or completion of home work while others would disagree to this as good educational practice. Primarily effort and overall knowledge reflection are the opposing concerns.

Proponents for such grading criteria suggest doing so gives students incentives to try. If such requirements aren't expected, the students would have little to work towards. Considering an overall grade influenced by such acts as participating in class encourages involvement which may potentially heighten a learning experience. In addition, students may see a completed homework assignment rewarding and will have a sense of accomplishment with a final product.

Conversely, opponents view these not as perks but rather downfalls to an overall knowledge development. Requiring such assignments may cause anxiety to get a good grade on homework with the knowledge that doing poorly can affect their grades. This anxiety may be a total disruption hindering the student from concentration. Proponents also believe that grades should only be

determined by reflecting on what a student has learned. If such mandates were determined, concepts may be taught to the homework as opposed to an overall learning, narrowing the scope of each subject. Also, students might begin to compare work with one another, building a competitive attitude.

. . . In my opinion, I believe participation, effort, and homework completion should influence an overall grade. *Students are at a young age they need goals set for them and incentives monitoring progress. Some students are by nature reclusive; with the notion of participation, students may open up more than they have otherwise. Giving expectations of students can push them to achieve better.* It is a proper way to monitor and reflect on our teaching, providing useful information. Educational practice considering these factors, and not based solely on these requirements, can be beneficial for both students and educators. [Italic emphasis added, indicating elaboration and additional points in first paragraph relating to incentives.]

## Low Publication Prices for APA Members and Affiliates

**Keeping you up-to-date.** All APA Fellows, Members, Associates, and Student Affiliates receive—as part of their annual dues—subscriptions to the *American Psychologist* and *APA Monitor*. High School Teacher and International Affiliates receive subscriptions to the *APA Monitor*, and they may subscribe to the *American Psychologist* at a significantly reduced rate. In addition, all Members and Student Affiliates are eligible for savings of up to 60% (plus a journal credit) on all other APA journals, as well as significant discounts on subscriptions from cooperating societies and publishers (e.g., the American Association for Counseling and Development, Academic Press, and Human Sciences Press).

**Essential resources.** APA members and affiliates receive special rates for purchases of APA books, including the *Publication Manual of the American Psychological Association*, and on dozens of new topical books each year.

**Other benefits of membership.** Membership in APA also provides eligibility for competitive insurance plans, continuing education programs, reduced APA convention fees, and specialty divisions.

**More information.** Write to American Psychological Association, Membership Services, 750 First Street, NE, Washington, DC 20002-4242.

# Predictors of Word Decoding and Reading Fluency Across Languages Varying in Orthographic Consistency

George K. Georgiou and Rauno Parrila  
University of Alberta

Timothy C. Papadopoulos  
University of Cyprus

Very few studies have directly compared reading acquisition across different orthographies. The authors examined the concurrent and longitudinal predictors of word decoding and reading fluency in children learning to read in an orthographically inconsistent language (English) and in an orthographically consistent language (Greek). One hundred ten English-speaking children and 70 Greek-speaking children attending Grade 1 were examined in measures of phonological awareness, phonological memory, rapid naming speed, orthographic processing, word decoding, and reading fluency. The same children were reassessed on word decoding and reading fluency measures when they were in Grade 2. The results of structural equation modeling indicated that both phonological and orthographic processing contributed uniquely to reading ability in Grades 1 and 2. However, the importance of these predictors was different in the two languages, particularly with respect to their effect on word decoding. The authors argue that the orthography that children are learning to read is an important factor that needs to be taken into account when models of reading development are being generalized across languages.

**Keywords:** reading development, longitudinal studies, cross-linguistic, psycholinguistic grain size theory

A wealth of evidence has established the prominent role of phonological processing in reading acquisition. Three different aspects of phonological processing—phonological awareness, phonological short-term memory, and rapid automatized naming (RAN)—predict the rate of reading acquisition in several alphabetic languages varying in orthographic consistency (e.g., de Jong & van der Leij, 1999; Holopainen, Ahonen, & Lyytinen, 2001; Muter, Hulme, Snowling, & Stevenson, 2004; Parrila, Kirby, & McQuarrie, 2004; Wagner & Torgesen, 1987). Researchers have tended to assume that the models of early reading development generalize across languages (e.g., Frith, 1985; Marsh, Friedman, Welch, & Desberg, 1981) despite the lack of cross-linguistic studies. In addition, little is known about the role of orthographic processing, defined as the ability to use visual-orthographic information in processing words in early reading development (e.g., Barker, Torgesen, & Wagner, 1992; Burt, 2006). We suggest that recent theoretical developments, the psycholinguistic grain size theory (PGST) and the theories of how RAN is related to reading, lead to expectations that both phonological processing and orthographic processing skills contribute differently to reading development in languages varying in orthographic consistency. In what follows, we first review the PGST, the RAN theories, and the predictions derived from them. We then summarize results of studies on the effects of phonological and orthographic processing

skills on reading across languages. Finally, we present an overview of the current study.

## The Psycholinguistic Grain Size Theory of Reading Development

Recently, Ziegler and Goswami (2005) introduced the psycholinguistic grain size theory (PGST), according to which “the dramatic differences in reading accuracy and reading speed found across orthographies reflect fundamental differences in the nature of the phonological recoding and reading strategies that are developing in response to the orthography” (p. 19). On one hand, children who are learning to read in orthographically consistent languages, such as Finnish, Greek, German, or Italian, rely heavily on grapheme–phoneme recoding strategies because the relationship between graphemes and phonemes is straightforward. On the other hand, children learning to read in orthographically inconsistent languages, such as English or Danish, cannot rely on smaller grain sizes because inconsistency is much higher for smaller grapheme units than for larger units. The reduced reliability of small grain sizes leads children to develop flexible unit size recoding strategies, such as grapheme–phoneme correspondence, morphological units, analogy, and whole-word recognition. Ziegler and Goswami (2005) went as far as to suggest that “it might even be the case that some of the most sophisticated processing architecture (e.g., two separate routes to pronunciation in the skilled reading system) may in fact only develop in English” (p. 20).

By making a distinction between the strategies employed by readers learning different orthographies to explain the cross-linguistic differences in reading accuracy and fluency, PGST has implications for the role of phonological and orthographic processing skills on reading development. If reading in orthographically inconsistent languages relies upon effective use of multiple recod-

ing strategies, skill at phonological awareness and orthographic processing should be important for reading development because decoding in orthographically inconsistent languages depends not only on the recognition of single graphemes and the retrieval of their corresponding sounds but also on the recognition of bigger grain size units, such as rimes and their corresponding sound units. Whereas phonological awareness is *sine qua non* for the former, orthographic knowledge is also needed for the latter (Share, 1995). Similarly, if reading in consistent orthographies relies on a grapheme–phoneme recoding strategy, then phonological short-term memory should play a larger role in reading in these languages because the phonological information of each grapheme must be available for blending and word naming to be successful.

### RAN and Reading Fluency

The PGST does not support predictions regarding the role of RAN on reading. However, some of the current theories of RAN seem to lead to different predictions regarding how orthographic consistency should affect RAN's contribution to reading development. If RAN measures the ability to access and retrieve phonological representations from long-term memory, as suggested by Torgesen, Wagner, and their colleagues (e.g., Torgesen, Wagner, Rashotte, Burgess, & Hecht, 1997; Wagner & Torgesen, 1987; Wagner et al., 1997), then it should be more strongly related to reading in consistent orthographies because the phonological representation of each grapheme should be retrieved quickly enough for the grapheme–phoneme recoding strategy to be effective. On the contrary, if RAN measures the ability to form orthographic representations, as suggested by Bowers and her colleagues (Bowers, Golden, Kennedy, & Young, 1994; Bowers, Sunseth, & Golden, 1999; Sunseth & Bowers, 2002), then RAN should be more important for reading in orthographically inconsistent languages because for the larger grain size unit strategies to succeed the orthographic information of those units must be developed.

Similarly, PGST does not explain the mechanism by which reading fluency is accomplished. Wimmer (2006) criticized PGST for providing a rather time-limited perspective because in consistent orthographies children achieve high levels of accuracy after a few months of reading instruction, and the main characteristic of further development is not reading accuracy but reading fluency. If children in consistent orthographies do not switch reading strategies depending on the type of reading task (accuracy or fluency), then fluency can be achieved only if grapheme–phoneme decoding strategy use becomes faster. If this inference is correct, then orthographic processing skills should not predict fluency development any more than accuracy development, whereas RAN should be a prominent predictor of reading fluency, an argument consistent with the data (e.g., Caravolas, 2006; de Jong & van der Leij, 1999). In contrast, in inconsistent orthographies fluency can be achieved only if multiple unit size strategies become more reliable and readily available; this would likely demand the joint contribution of both RAN and orthographic processing skills.

Because of the recency of the PGST and the RAN theories, the above predictions have not been directly tested. In the rest of this introduction, we review indirect evidence for the predictions, derived mainly from studies using either a sample learning to read a single language or from studies using a limited set of predictors in a multilanguage sample.

### Orthographic Consistency and Phonological Processing

Cross-sectional and longitudinal studies conducted in languages varying in orthographic consistency have produced conflicting findings as to the importance of each one of the phonological processing skills in reading acquisition. In English-speaking children, the contribution of phonological awareness appears to remain strong through elementary school, whereas the contribution of RAN appears to be time-limited and dependent on the type of RAN tasks used (Letter and Digit Naming vs. Color and Object Naming) and the reading competence of the children (e.g., Compton, 2003; Georgiou, Parrila, & Kirby, 2006; Meyer, Wood, Hart, & Felton, 1998; Schatschneider, Fletcher, Francis, Carlson, & Foorman, 2004). Finally, conflicting findings have been reported regarding the contribution of phonological short-term memory. For example, Swanson and his colleagues (e.g., Swanson & Alexander, 1997; Swanson & Howell, 2001) reported significant contributions of phonological short-term memory on reading, whereas others have shown that it is only weakly related to reading when considered along with phonological awareness and RAN (e.g., Parrila et al., 2004; Torgesen et al., 1997).

The majority of studies conducted in orthographically consistent languages have shown that phonological awareness either may not be an important predictor of reading (e.g., Aarnoutse, van Leeuwe, & Verhoeven, 2005; Harris & Giannouli, 1999; Holopainen et al., 2001) or may be important but only during the first 1 or 2 years of schooling (e.g., de Jong & van der Leij, 2002; Landerl & Wimmer, 2000; Leppänen, Niemi, Aunola, & Nurmi, 2006; Papadopoulos, 2001). Researchers hypothesized that the effect of consistent spelling–sound correspondences is sufficiently powerful to secure children's phonological recoding skills after a few months of reading experience, regardless of their prereading levels of phonological awareness (e.g., Caravolas, 2006; Porpodas, 1999; Wimmer, Landerl, & Schneider, 1994). Accordingly, several studies have suggested that RAN plays a more prominent role than phonological awareness in predicting reading development in consistent orthographies (e.g., de Jong & van der Leij, 1999, 2002; Mayringer, Wimmer, & Landerl, 1998; van den Bos, 1998; Wimmer, Mayringer, & Landerl, 2000). Finally, phonological short-term memory appears to play a trivial role in learning to read in orthographically consistent languages (e.g., de Jong & van der Leij, 1999; Nikolopoulos, Goulondris, Hulme, & Snowling, 2006).

The few studies that directly compared children learning different alphabetic languages have also provided mixed findings. Patel, Snowling, and de Jong (2004) compared the predictors of reading ability in English and Dutch and found that “the concurrent predictors of reading in English and Dutch were *strikingly similar* [italics added]” (p. 793). Phoneme deletion was a significant predictor of individual differences in reading, but RAN was not. The authors concluded that phonological awareness is a predictor of individual differences in reading skill in both transparent and opaque orthographies. However, the language by phoneme deletion interaction accounted for significant variance in word-reading accuracy after the effects of language, age, vocabulary, phoneme deletion, and RAN were controlled; follow-up analyses revealed that phoneme deletion was a significant predictor of word-reading accuracy only for the English children.

Mann and Wimmer (2002) examined the predictors of reading in English and German. At the end of kindergarten, Grade 1, and

Grade 2, children were given two tests of phonological awareness (Phoneme Identity Judgment and Phoneme Elision), RAN-Colors, letter identification, and short tests of word and nonword-reading accuracy and speed. Regression analyses showed that the only significant predictor of both reading accuracy and speed in English was phonological awareness. In German, there were no significant predictors of reading accuracy, whereas RAN was the only significant predictor of reading speed. Although Mann and Wimmer's (2002) results may reflect genuine differences in the extent to which reading acquisition relies on different processes, there are notable methodological problems that may compromise this conclusion. First, lack of variability in word and nonword-reading accuracy scores was evident in the German sample. Second, there was lack of variability in Phoneme Identity Judgment, a task used to create a composite phonological awareness score, which was, in turn, used to predict reading accuracy and speed.

Recently, Caravolas, Vólin, and Hulme (2005) suggested that when phonological awareness is measured with sufficiently difficult tasks, a significant contribution of phonological awareness on reading ability in regular orthographies can be detected even with older children. Caravolas et al. (2005) examined the effect of phonological awareness on reading and spelling in a regular orthography (Czech) and in an opaque orthography (English) in a group of normally developing children in Grades 2 to 5 (Czech sample) and Grades 2 to 7 (English sample). Phonological awareness, measured by Phoneme Elision and spoonerisms tasks, was a significant predictor of reading ability in both Czech and English.

To summarize, studies have provided contradictory findings on the contribution of phonological processing skills on reading across alphabetic languages that vary in orthographic consistency. The selection of tasks may moderate the relationship between phonological awareness, RAN, and reading. First, many phonological awareness tasks, such as rhyme awareness or phoneme judgment, are likely too easy for Grade 1 students in orthographically consistent languages, producing a ceiling effect. In contrast, a task such as Phoneme Elision is more difficult and is more likely to create variability in older readers. Second, alphanumeric RAN tasks (Digit and Letter Naming) in many single-language studies are stronger predictors of reading than nonalphanumeric RAN tasks (Color and Object Naming; e.g., Bowey, McGuigan, & Ruschena, 2005; Compton, 2003; Felton & Brown, 1990). Yet, no cross-linguistic studies used alphanumeric RAN tasks, possibly underestimating the RAN-reading relationship.

It is also possible that the differences found in the predictive value of the phonological processing skills may be partly due to the measures used to assess reading ability. Research in English-speaking populations has primarily focused on the prediction of reading accuracy, whereas research conducted in orthographically consistent languages has primarily focused on the prediction of individual differences in reading speed. Wolf and Bowers (1999) argued that phonological awareness is more strongly related to word-reading accuracy, and RAN is more strongly related to reading fluency (see also Bowers, 1995; Katzir et al., 2006; Manis, Doi, & Bhadha, 2000; Savage & Frederickson, 2005). Thus, to the extent that phonological awareness and RAN are differentially related to specific types of reading outcomes, then the use of reading-speed measures in consistent orthographies might have accentuated the role of RAN and the use of reading-accuracy

measures in inconsistent orthographies might have accentuated the role of phonological awareness.

### Orthographic Consistency and Orthographic Processing

The role of orthographic processing in predicting reading development is not yet fully understood. Confusion arises because of differences in the way orthographic processing has been conceptualized and operationalized (Burt, 2006; Hagiliassis, Pratt, & Johnston, 2006). Impressively, Wagner and Barker (1994) provided 11 definitions of orthographic processing used in research. For example, Stanovich and West (1989) defined orthographic processing as "the ability to form, store, and access orthographic representation(s)" (p. 404); and Perfetti (1984) defined it as "the knowledge a reader has about permissible letter patterns" (p. 47). In this study, we define orthographic processing as children's sensitivity to the orthographic structure of words.

Several studies have demonstrated orthographic processing's impact on reading acquisition in English (e.g., Badian, 2001; Cunningham, Perry, & Stanovich, 2001; Cutting & Denckla, 2001; Holland, McIntosh, & Huffman, 2004; Torgesen et al., 1997). For example, Torgesen et al. (1997) showed that orthographic processing accounted for a significant amount of unique variance in Grades 4 and 5 word-reading accuracy and reading comprehension.

Related studies conducted in other languages are rare, are confounded by bilingualism, and have produced conflicting results. For example, Arab-Moghaddam and Sénéchal (2001) examined the effects of phonological and orthographic processing skills on reading in English and Persian, an orthographically consistent language. Persian-speaking children in Grades 2 and 3 who had lived in English-speaking Canada for an average of 4 years were tested on word reading in English and Persian. Investigators found that the predictors of reading performance were similar across languages: Phonological and orthographic processing skills each accounted for unique variance in word reading in English and Persian once other related variables were controlled. Importantly, in both languages, the amount of unique variance accounted for by orthographic processing was twice the amount accounted for by phonological processing.

Geva, Wade-Woolley, and Shany (1993) studied children learning to read both English and vowelized Hebrew, which has almost perfect grapheme-to-phoneme correspondences. Although both phonological and orthographic processing predicted reading acquisition in English, only phonological skills predicted reading acquisition in Hebrew. These contrasting findings suggest that whereas orthographic processing contributes significantly to reading acquisition in English, its role is unclear in consistent orthographies.

### Overview of the Current Study

Several researchers have argued that in order for them to have a comprehensive understanding of the mechanisms involved in reading (e.g., Aro & Wimmer, 2003; Goswami, 1999; Harris & Hattano, 1999), models of reading development should be tested across languages varying in orthographic consistency. In response, the current study sought to compare concurrently and longitudinally the relative importance of phonological processing (phonological awareness, phonological memory, and RAN) and ortho-

graphic processing in predicting word-reading accuracy and fluency in children learning to read an orthographically consistent language (Greek) and in children learning to read an orthographically inconsistent language (English).

Within the family of alphabetic scripts, Greek provides an interesting contrast to English because of its high degree of regularity for reading. Although in Greek there are no statistical estimations of the degree of regularity, the almost perfect one-to-one correspondence between its graphemes and phonemes (see Porpodas, 2004, for a description of a few exceptions) and the predominance of open consonant-vowel syllables render Greek orthography consistent.

## Method

### Participants

Letters describing the study were sent to parents of 161 Grade 1 English-speaking Canadian and 92 Grade 1 Greek-speaking Cypriot children. One hundred thirty-two English-speaking children (70 girls and 62 boys, mean age = 79.48 months,  $SD = 3.98$ ) and 75 Greek-speaking children (42 girls and 33 boys, mean age = 82.20 months,  $SD = 3.33$ ), whose parents consented to participate in the study, were followed from Grade 1 to Grade 2. They were all native speakers of English and Greek, respectively. The Canadian children were assessed in April/May of Grade 1 and January/February of Grade 2, whereas the Cypriot children were assessed in April/May of Grade 1 and Grade 2, respectively. By Grade 2 the sample consisted of 110 English-speaking children (59 girls and 51 boys, mean age = 79.52 months,  $SD = 4.01$ ) and 70 Greek-speaking children (40 girls and 30 boys, mean age = 83.06 months,  $SD = 3.35$ ). Twenty-two English-speaking children (16.6% of the sample) and 5 Greek-speaking children (6.6% of the sample) withdrew from the study. To examine if the performance of the children who withdrew from the study differed significantly from the rest of the children, we performed  $t$  tests on their Grade 1 performance scores. None of the  $t$  tests reached significance for either English-speaking (all  $ps > .12$ ) or Greek-speaking (all  $ps < .08$ ) children. All the subsequent analyses were conducted with the children who were assessed at both measurement points. The children in both countries were coming mostly from families of middle-to-upper-middle socioeconomic status. None of the children participating in this study were identified as having learning, emotional, or sensory disabilities.

### Reading Instruction

Formal instruction in reading in Cyprus, where the data for the Greek-speaking children were collected, begins at the start of Grade 1, when children are, on average, 6 years of age. It emphasizes grapheme-phoneme correspondences or other letter combination patterns (i.e., digraphs). The whole language approach is also in use with the intention of building sight vocabulary. Grammatical and syntactic rules are introduced at the end of Grade 1 and are taught systematically from Grade 2 onward. The method of reading instruction in Alberta, where the data for the English-speaking children were collected, also emphasizes both grapheme-phoneme correspondences and whole-word recognition strategies. This combined method of reading instruction is known as the

Balanced Literacy Program (see Sénéchal & LeFevre, 2002; Sénéchal, LeFevre, Thomas, & Daley, 1998).

## Materials

Due to the cross-linguistic nature of the study, we decided to use those phonological awareness, phonological memory, and RAN measures that have been shown to be robust predictors of early reading in both English and Greek and that have similar or comparable versions for both languages. Similarly, we selected the orthographic, nonword-reading, and reading-fluency tasks in English for which comparable tasks could be developed in Greek.

### Phonological Awareness

In English, Elision, adopted from the Comprehensive Test of Phonological Processes (CTOPP; Wagner, Torgesen, & Rashotte, 1999), was used to measure phonological awareness. There were 3 practice items and 24 test items. Four test items required the participant to say the word without saying one of the syllables, and the remaining 20 items required the participant to say a word without saying a designated sound in the word. The position of the phoneme to be removed varied across those 20 items; in eight cases it involved the initial phoneme (e.g., *farm* without the /f/ is *arm*); in six cases, the medial phoneme (e.g., *winter* without the /t/ is *winner*), and in six cases, the final phoneme (e.g., *sheep* without the /p/ is *she*). Testing was discontinued after three consecutive errors. A participant's score was the number of correct items. The split-half reliability coefficient in our English-speaking sample was .92.

The Greek version of Elision had the same number of items as the English task. However, given that the items after the deletion of a phoneme must produce a real word and that, in contrast to the majority of the English words, the typical Greek words are two or more syllables, complete matching of the words in the two languages was impossible. Instead, we devised a list of items that required the children to delete the same sound (initial, medial, final) from the word as it was required from the English-speaking children. Specifically, four test items required the participant to say the word without saying one of the syllables (e.g., λεμόνι /lemoni/ [lemon] without the /le/ is μόνη /moni/ [alone]), eight test items required the participant to delete the initial phoneme (e.g., πόλη /poli/ [town] without the /p/ is όλοι /oli/ [all]); six test items required the participant to delete the medial phoneme (e.g., δίνω /dino/ [give] without the /n/ is δύο /dio/ [two]), and six test items required the participant to delete the final phoneme (e.g., ζώα /zoa/ [animals] without the /a/ is ζω /zo/ [live]). Testing was discontinued after three consecutive errors. A participant's score was the number of correct items. The split-half reliability coefficient of Phoneme Elision in our Greek-speaking sample was .91.

### Naming Speed

**Color Naming.** This task required participants to state as quickly as possible the names of five colors (blue, black, green, red, or yellow). The colors were presented on a laptop computer screen and arranged randomly in five rows with ten colors per row on two separate pages. Prior to beginning the timed naming, each participant was asked to name the colors in a practice trial to

ensure familiarity. The two pages were timed separately. Wolf and Denckla (2005) reported test-retest reliability of Color Naming to be .90. Color Naming in Greek was administered the same way as in English. The corresponding names of colors in Greek are μπλε (*mble*) for blue, μαύρο (*mavro*) for black, πράσινο (*prasino*) for green, κόκκινο (*kokkino*) for red, and κίτρινο (*kitrino*) for yellow. The mean phoneme length for the Greek color names was 5.6, whereas for the English it was 3.6. This difference was significant,  $t(8) = 2.54, p < .05$ .

**Digit Naming.** This task was adopted from CTOPP (Wagner et al., 1999). This RAN task consisted of a set of six digits (4, 7, 8, 5, 2, 3) that were displayed in random sequence six times for a total of 36 stimuli. Subjects were asked to name the digits from left to right as quickly as possible. The total time to completion was recorded. Before naming the 36 digits, each participant was asked to name the six digits in a practice trial to ensure familiarity. Wagner et al. (1999) reported test-retest reliability of .91 for Digit Naming for children ages 5 to 7 years. Digit Naming in Greek was administered in the same way as in English. The corresponding names of digits in Greek are τέσσερα (*tessera*) for four, επτά (*epta*) for seven, οκτώ (*okto*) for eight, πέντε (*pende*) for five, δύο (*dio*) for two, and τρία (*tria*) for three. The mean phoneme length for the Greek digit names was 4.8, whereas for the English it was 3.6. This difference was not significant,  $t(10) = 1.43, ns$ .

### Phonological Memory

Forward Digit Span from the Wechsler Intelligence Scale for Children-Third Edition (WISC-III; Wechsler, 1992) was used to assess phonological short-term memory in both language groups. The strings of digits were presented orally with a time interval of about 0.5 s between each digit. The child had to repeat the digits in each string in correct order. The strings started with only two digits, and one digit was added for each new digit string. The task was terminated when the child failed both trials of a given length. The performance score was the number of digit strings that the child could accurately provide. Split-half reliability coefficient for this task in our English-speaking sample was .69, whereas the corresponding reliability coefficient in our Greek-speaking sample was only .51.

### Orthographic Processing

The Orthographic Choice task was adapted from the work of Olson and colleagues (e.g., Olson, Forsberg, Wise, & Rack, 1994; Olson, Wise, Conners, Rack, & Fulker, 1989). The students viewed pairs of letter strings that sounded alike (e.g., rain - rane) and were asked to circle the one that was spelled correctly. Thirty pairs of phonologically similar letter strings were presented to the children on a sheet of paper. An individual's score was the number of correctly circled real words. Cronbach's alpha for Orthographic Choice in our English-speaking sample was .80. The Orthographic Choice test in Greek had the same number of items as in English. However, given that irregularity in Greek orthography can be found only in the spelling of the phonemes /o/, /i/, and /ε/, the selected real words and their pseudohomophones differed only in the way that the aforementioned phonemes were represented (e.g., /σχολείο/ [school] versus /σχολβο/). Cronbach's alpha in our Greek-speaking sample was .87.

### Nonword Reading

Form H Word Attack from Woodcock Reading Mastery Tests-Revised (WRMT-R; Woodcock, 1998) was used to assess decoding in Grades 1 and 2. Participants were asked to read 45 nonwords presented on a laptop screen as if they were real English words. The number of characters in the English Word Attack task was 215. Testing was discontinued after six consecutive errors. A participant's score was the number of items correct. Split-half reliability coefficient in our sample was .94 for Grade 1 and .93 for Grade 2, respectively.

Similar to its original version in English, the Greek Word Attack task consisted of 45 pronounceable nonwords that were derived from real words after changing two or three letters (either by substituting them or using them backwards). It was originally piloted in a study by Papadopoulos and Georgiou (2000) and was later used in other studies, showing satisfactory psychometric properties in its Greek version with both typically developing populations (e.g., Papadopoulos, 2001) and children exhibiting reading difficulties (e.g., Papadopoulos, Chalarambous, Kanari, & Loizou, 2004). The number of characters in the Greek Word Attack task was 218. Testing was discontinued after six consecutive errors. A participant's score was the number of items correct. Split-half reliability coefficient in our sample was .94 in Grade 1 and .87 in Grade 2, respectively.

### Reading Fluency

Gray Oral Reading Test (GORT; Wiederholt & Bryant, 2001) was used to assess subjects' text-reading fluency. The participants were asked to read as fast and as accurately as possible two short stories whose content was familiar to both North American and Cypriot children. The reading comprehension questions that follow each story were not administered because it was not the intention of this study to examine reading comprehension. Children's score was the total time taken to read the two short stories. Wiederholt and Bryant (2001) reported test-retest reliability for GORT to be .93. The Greek version of this task was a translation/back translation of the English GORT. Thus, although attention was paid to ensure that the words in the translated texts were of the same difficulty as in English, passage length across languages was dissimilar. The English GORT contained 61 words for a total of 232 characters, whereas the Greek GORT contained 53 words for a total of 281 characters.

Test of Word Reading Efficiency (TOWRE; Torgesen, Wagner, & Rashotte, 1999) was used to assess subjects' word-reading fluency. The child was given a list of 104 words, divided into four columns of 26 words each, and asked to read them as fast as possible. A short, 8-word practice list was presented first. The number of words read correctly and the number of errors made within a 45-s time limit was recorded. The score was the number of words read correctly. Torgesen et al. (1999) reported test-retest reliability of .95 for ages 6 to 9 years. The Greek version of this task had the same format as the English one. It consisted of 104 words beginning with one-syllable words and ending with three-syllable words. However, the Greek version of the task had longer words compared with the English task. More specifically, although the Greek TOWRE contained 644 characters, the English TOWRE contained 607 characters.

### Procedure

In Grade 1, the children were administered measures of phonological awareness, rapid-naming speed, phonological memory, orthographic processing, word decoding, and reading fluency. In Grade 2, only the dependent measures of word decoding and reading fluency were administered. All participants were tested individually in their respective schools during school hours by trained experimenters. Testing in Grade 1 was divided into two sessions lasting roughly 30 to 40 min. Session A consisted of Color Naming, Elision, Digit Naming, and Word Attack. Session B consisted of Digit Span, Orthographic Choice, TOWRE, and GORT. Half of the participants in each language group received first Session A, whereas the other half received first Session B. The order of the tasks within each session was fixed.

### Statistical Analysis

To examine the contribution of different predictors on reading accuracy and fluency both concurrently and longitudinally, we used structural equation modeling (SEM). Maximum likelihood estimation procedures were used to analyze the variance/covariance matrix of the observed variables using AMOS 7.0 (Arbuckle, 2006). To evaluate model fit, chi-square values and a set of fit indexes were used as follows: (a) the comparative fit index (CFI); (b) the goodness of fit index (GFI); and (c) the root-mean-square error of approximation (RMSEA). Nonsignificant chi-square, CFI, and GFI indices above .95 suggest model acceptance (Hu & Bentler, 1999). RMSEA values below or at .05 indicate a close fit but values as high as .07 are regarded as acceptable (Browne & Cudeck, 1993).

Separate models were constructed with Word Attack, TOWRE, and GORT as the outcome variables. The first step was to estimate the fit of a baseline model, depicted in Figure 1, with all possible correlations between the predictor variables (Elision, Digit Span, RAN-Digits, and Orthographic Choice) and all possible paths from the predictor variables to the outcome variable present in Grades 1 and 2 (Word Attack, TOWRE, and GORT) separately for English and Greek. Age was included as a control variable, but it was not allowed to correlate with other predictor variables in the model. Given that the models are close to saturated, we expected that they would provide an almost perfect fit to the data (e.g., Hayduk,

1986). To increase the degrees of freedom and examine whether the most parsimonious well-fitting models are similar in the two languages, nonsignificant correlations and regression paths were dropped one at a time until all remaining paths in the models were significant. Age was retained in all models as a control variable.

Next, we examined the cross-linguistic differences by performing multigroup analyses. To increase the degrees of freedom in the tested models, only those correlations between the predictor variables and paths from the predictor variables to the outcome measures that were significant in one or both of the languages were retained. We then tested first the fit of a multigroup model in which no cross-language constraints were imposed. This was followed by testing the invariance of the regression paths in the two language groups by imposing equality constraints on the direct effects of the predictor variables on Word Attack, TOWRE, and GORT. Specifically, regression paths were constrained in a step-wise fashion in which the direct effects of Elision on the reading outcomes were constrained first. In testing for the invariance of the regression paths, we compared the chi-square value of the constrained model with that of the initial multigroup model in which no cross-language constraints were imposed. If the difference in chi-square values, given the difference in the degrees of freedom between the two models ( $df$  constrained –  $df$  unconstrained), was significant, then this indicated that the specific predictor was contributing in a different way to the outcome variable in the two languages. Next, we examined, one at a time, the invariance of the regression paths of Digit Span, RAN-Digits, and Orthographic Choice on the reading outcomes following the same procedure. Testing for invariance was performed in the same way as described above for Elision.

Finally, we obtained estimates of total effects, or the sum of direct (unmediated) and indirect (mediated) effects, on Grade 2 reading outcomes. The SEM analysis model displayed in Figure 1 was fitted to the data three times for each language, first with Grade 2 word decoding accuracy (Word Attack) as the dependent variable and then with word-reading fluency (TOWRE) and text-reading fluency (GORT) scores as the dependent variables, respectively.

## Results

### Preliminary Data Analysis

Descriptive statistics for the entire sample of English and Greek children are shown in Table 1. One English- and 5 Greek-speaking children failed to name all the colors and were thus not administered the RAN-Colors task. Similarly, 2 English- and 2 Greek-speaking children could not complete GORT in Grade 1. In order to examine if there were significant differences between the two groups on age, we performed  $t$  tests. The results revealed that the Greek-speaking children were significantly older than the English-speaking children both in Grade 1,  $t(178) = 6.13$ ,  $p < .001$ , Cohen's  $d = 0.94$ , and in Grade 2,  $t(178) = 7.02$ ,  $p < .001$ , Cohen's  $d = 1.21$ .

A closer look at the distributional properties of the variables revealed some problems. The rapid naming speed tasks were positively skewed. Log transformations were applied to reach normality. The distribution of Orthographic Choice was negatively skewed. Reflection plus square-root transformation was

performed to reach normality. Despite the effectiveness of the transformations, some of the measures were still affected by the presence of outliers. More specifically, performances of 3 English-speaking and 4 Greek-speaking children were outliers on RAN-Digits and performances of 3 English-speaking and 2 Greek-speaking children were outliers on RAN-Colors. The outliers in both tasks were located at the high end of the distribution, indicating slow performance. In order to reduce the possible effect of outliers, we replaced their responses by a value equal to the next highest nonoutlier score plus one unit of measurement (Tabachnick & Fidell, 2001). The outlier's ranking within the distribution was preserved without deleting the datum or permitting its skewing influence. The transformed scores were used in all further analyses.

Table 2 displays the correlations between all the measures by language group. A similar pattern of correlations is observable in the two languages between the independent measures and reading. RAN-Digits was strongly related to reading fluency across languages and phonological awareness was strongly related to word

decoding in English. Orthographic Choice was strongly related to both word decoding and fluency measures across languages. Phonological memory was moderately related to different reading outcomes in English. The dependent measures of word decoding and fluency showed high stability from Grade 1 to Grade 2.

### *Predictors of Word Decoding*

To examine the predictors of word decoding, the baseline model (Figure 1) was fitted to the data with Grade 1 and Grade 2 Word Attack scores as the dependent variables. As was expected, the model fitted the data very well,  $\chi^2(4, N = 110) = 0.62, p = .892$ , CFI = 1.00, GFI = .99, RMSEA = .00, for English, and  $\chi^2(4, N = 70) = 1.44, p = .838$ , CFI = 1.00, GFI = .99, RMSEA = .00, for Greek, respectively. RAN-Digits was used as a measure of rapid naming speed because, in both languages, it produced generally larger correlations with the dependent variables than RAN-Colors. Next, we deleted one at a time the nonsignificant paths to produce the most parsimonious model in which Word Attack was the dependent variable in each language. Figure 2 shows the final models. The models provided a good fit to the data,  $\chi^2(7, N = 110) = 3.48, p = .837$ , CFI = 1.00, GFI = .99, RMSEA = .00, for English, and  $\chi^2(10, N = 70) = 5.45, p = .859$ , CFI = 1.00, GFI = .97, RMSEA = .00, for Greek, respectively, and accounted for a moderate proportion of the variance in Grade 1 (English:  $R^2 = .58$ ; Greek:  $R^2 = .41$ ) and a high proportion of the variance in Grade 2 for English ( $R^2 = .83$ ), but not for Greek ( $R^2 = .38$ ). There were two significant predictors of Grade 1 Word Attack in English: Elision and Orthographic Choice, and three significant predictors of Grade 1 Word Attack in Greek: Elision, Digit Span, and RAN-Digits. Not surprisingly, there was a strong autoregressive path from Word Attack in Grade 1 to Word Attack in Grade 2 in both languages. However, even after controlling for the autoregressive effect, Elision and RAN-Digits measured in Grade 1 were significant predictors of Word Attack in Grade 2 in English. In Greek, Word Attack in Grade 1 was the only significant predictor of Word Attack in Grade 2. It should be noted that given the strong autoregressive effect in both languages, the evaluation of

other longitudinal predictors of Grade 2 Word Attack is highly conservative.

After establishing the most parsimonious model for each language separately, we used multigroup analyses to examine if there were any differences across the two languages in the significant predictors of Word Attack. The unconstrained multigroup model included all paths that were significant in either or both of the models shown in Figure 2 and fitted the data very well,  $\chi^2(10, N = 170) = 3.87, p = .953$ , CFI = 1.00, GFI = .99, RMSEA = .00.

Table 3 presents the changes in  $\chi^2$  values when predictors of interest were constrained to be equal across the languages. The fit of the multigroup model deteriorated significantly when the direct effects of Elision,  $\Delta\chi^2 = 8.79, p < .01$ , or Orthographic Choice,  $\Delta\chi^2 = 18.33, p < .001$ , on Grade 1 Word Attack were so constrained. In contrast, when the direct effects of Digit Span or RAN-Digits were constrained, there were no significant changes in model fit. For Word Attack in Grade 2, only constraining the direct effects of Elision,  $\Delta\chi^2 = 4.92, p < .05$ , and Word Attack in Grade

1,  $\Delta\chi^2 = 6.09, p < .05$ , resulted in a significantly poorer fitting model. Thus, these results indicate that Elision is a stronger predictor of Word Attack in English than in Greek both concurrently and longitudinally. Orthographic Choice, in turn, is a strong concurrent predictor of Grade 1 Word Attack in English only. Finally, the autoregressive effect of Grade 1 Word Attack on Grade 2 Word Attack was stronger in English than in Greek.

### Predictors of Word-Reading Fluency

The second set of analyses examined the predictors of TOWRE in Grade 1 and Grade 2. The baseline models fitted the data very well,  $\chi^2(4, N = 110) = 0.63, p = .890$ , CFI = 1.00, GFI = 1.00, RMSEA = .00, for English, and  $\chi^2(4, N = 70) = 1.48, p = .829$ , CFI = 1.00, GFI = .99, RMSEA = .00, for Greek, respectively. The most parsimonious model in each language is shown in Figure 3. The models provided a good fit to the data,  $\chi^2(7, N = 110) = 3.45, p = .840$ , CFI = 1.00, GFI = .99, RMSEA = .00, for

\* $p < .05$ . \*\* $p < .01$ . \*\*\* $p < .001$ .

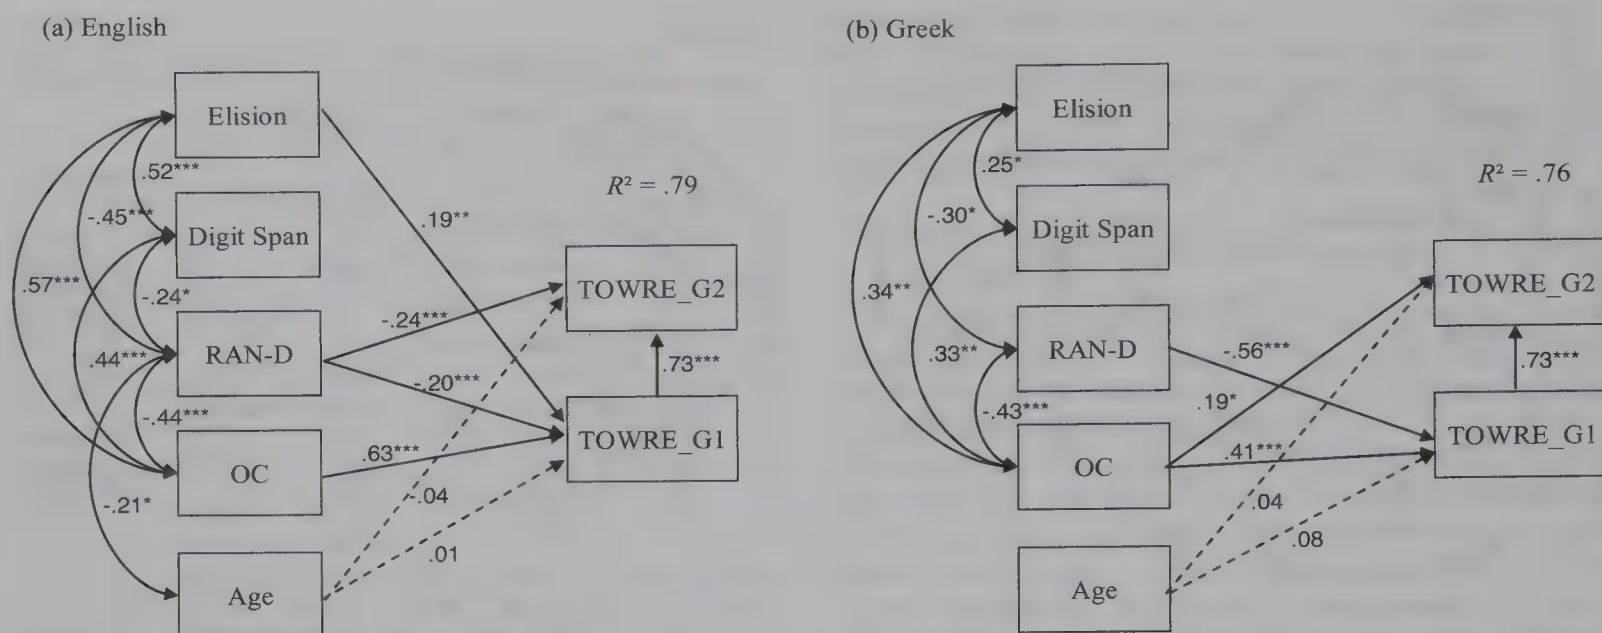

Figure 3. The baseline path model of predictors of the Test of Word Reading Efficiency (TOWRE) in Grade 2 in English (a) and Greek (b). RAN-D = Rapid Automatized Naming-Digits; OC = Orthographic Choice; G1 = Grade 1; G2 = Grade 2. \* $p < .05$ . \*\* $p < .01$ . \*\*\* $p < .001$ .

English, and  $\chi^2(10, N = 70) = 3.93, p = .950$ , CFI = 1.00, GFI = .98, RMSEA = .00, for Greek, respectively, and accounted for a high proportion of the variance in Grade 1 TOWRE (English:  $R^2 = .75$ ; Greek:  $R^2 = .68$ ) and Grade 2 TOWRE (English:  $R^2 = .79$ ; Greek:  $R^2 = .76$ ). There were three significant predictors of Grade 1 TOWRE in English: Elision, RAN-Digits, and Orthographic Choice; there were two unique predictors of Grade 1 TOWRE in Greek: RAN-Digits and Orthographic Choice. Longitudinally, there was a strong autoregressive path from Grade 1 TOWRE to Grade 2 TOWRE for both English and Greek. Despite the strong autoregressive effect, RAN-Digits in English and Orthographic Choice in Greek accounted for additional variance in Grade 2 TOWRE.

Next, we examined the cross-linguistic differences in the predictors of TOWRE. The unconstrained multigroup model,  $\chi^2(12, N = 170) = 5.23, p = .950$ , CFI = 1.00, GFI = .99, RMSEA = .00, included all paths that were significant in either or both of the models shown in Figure 3. When the direct effects of Elision,  $\Delta\chi^2 = 4.98, p < .05$ , RAN-Digits,  $\Delta\chi^2 = 8.15, p < .01$ , or Orthographic Choice,  $\Delta\chi^2 = 10.93, p < .01$ , on Grade 1 TOWRE were constrained to be equal across the two languages, the model fit deteriorated significantly. When the direct effect of RAN-Digits,  $\Delta\chi^2 = 6.86, p < .05$ , on Grade 2 TOWRE was constrained to be equal, the model fit also deteriorated significantly whereas the same was not true when the effect of Orthographic Choice or Grade 1 TOWRE was constrained. Thus, these analyses indicate that RAN-Digits exerts a significantly stronger effect in Greek than in English, and that Elision and Orthographic Choice were stronger predictors of Grade 1 TOWRE in English than in Greek.

#### Predictors of Text-Reading Fluency

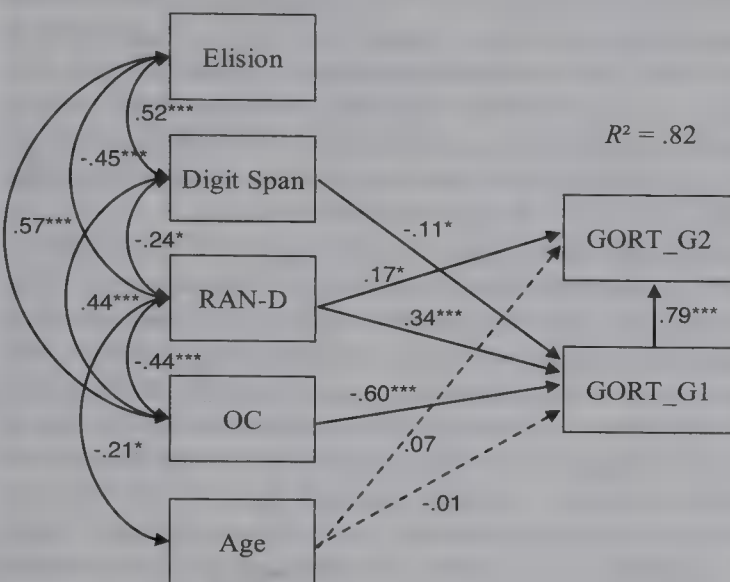

The third set of analyses examined the predictors of GORT in Grades 1 and 2. The baseline models fitted the data very well,  $\chi^2(4, N = 110) = 0.63, p = .990$ , CFI = 1.00, GFI = 1.00, RMSEA =

.00, for English, and  $\chi^2(4, N = 70) = 1.48, p = .829$ , CFI = 1.00, GFI = .99, RMSEA = .00, for Greek, respectively. Figure 4 presents the most parsimonious model for each language, each providing a good fit to the data,  $\chi^2(7, N = 110) = 4.45, p = .726$ , CFI = 1.00, GFI = .99, RMSEA = .00, for English, and  $\chi^2(10, N = 70) = 6.75, p = .748$ , CFI = 1.00, GFI = .98, RMSEA = .00, for Greek, respectively, and accounting for a high proportion of the variance in Grade 1 (English:  $R^2 = .75$ ; Greek:  $R^2 = .69$ ) and in Grade 2 (English:  $R^2 = .82$ ; Greek:  $R^2 = .71$ ). For both English and Greek, RAN-Digits and Orthographic Choice were the unique predictors of GORT in Grade 1. After controlling for the strong autoregressive path from GORT in Grade 1 to Grade 2, RAN-Digits in English and Orthographic Choice in Greek predicted unique variance in Grade 2 GORT.

Finally, we examined if there were any differences in the significant predictors of GORT across the two languages. The unconstrained multigroup model,  $\chi^2(12, N = 170) = 8.91, p = .711$ , CFI = 1.00, GFI = .99, RMSEA = .00, included all significant paths of the models shown in Figure 4. A significant change in model fit was observed when the effect of Orthographic Choice,  $\Delta\chi^2 = 11.75, p < .01$ , on Grade 1 GORT was constrained to be equal across the two languages. Similarly, constraining the path between RAN-Digits and Grade 2 GORT produced a significant change in the model fit,  $\Delta\chi^2 = 4.29, p < .05$ . Thus, similar to what we observed for TOWRE, Orthographic Choice was a better predictor of Grade 1 GORT in English than in Greek. In addition, RAN-Digits was a better predictor of Grade 2 GORT in English than in Greek.

To summarize, the SEM results demonstrated differences in the significant predictors of reading across languages. First, Elision appears to predict Word Attack better than it predicts TOWRE or GORT, and its contribution is greater in English than in Greek. Second, Digit Span was in most models a nonsignificant predictor of reading outcomes (with the exception of Grade 1 Word Attack in Greek and Grade 1 GORT in English). Third, RAN-Digits was

(a) English

(b) Greek

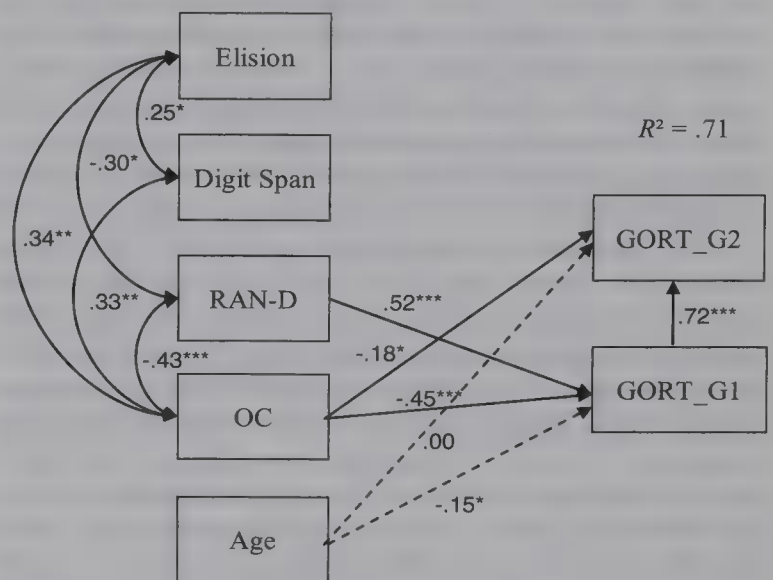

Figure 4. The baseline path model of predictors of the Gray Oral Reading Test (GORT) in Grade 2 in English (a) and Greek (b). RAN-D = Rapid Automatized Naming-Digits; OC = Orthographic Choice; G1 = Grade 1; G2 = Grade 2. \* $p < .05$ . \*\* $p < .01$ . \*\*\* $p < .001$ .

a stronger predictor of the reading fluency measures than of Word Attack. Notably, its effect on TOWRE in Grade 1 was stronger in Greek than in English. However, only in English did RAN-Digits have a direct effect on Grade 2 TOWRE and GORT. Fourth, Orthographic Choice was a stronger predictor of Grade 1 reading outcomes in English than in Greek. However, only in Greek did Orthographic Choice have a direct effect on Grade 2 TOWRE beyond the contribution of the autoregressor. Finally, many more similarities in the predictors were observed across languages in the reading fluency models than in the word decoding models.

#### Total Effects on Word Attack, TOWRE, and GORT in Grade 2

On several occasions, the above analyses indicated that the timing of the most significant effects may vary across the languages, creating an appearance of significant differences that may be short-lived. For example, in the TOWRE and GORT models for Greek-speaking children RAN-Digits predicted strongly Grade 1 reading performance but not Grade 2 performance, after the autoregressive effect was controlled. In contrast, similar models for the English-speaking children indicated that RAN-Digits predicted moderately both Grade 1 and Grade 2 reading outcomes. The opposite pattern, however, was observed for Orthographic Choice. These results leave open the possibility that in spite of initial significant differences between the languages, the total effect (the sum of direct and indirect effects) of RAN-Digits to Grade 2 reading fluency may be very similar.

Table 4 shows the standardized estimates of the total effects of Elision, RAN-Digits, Digit Span, and Orthographic Choice on Grade 2 Word Attack, TOWRE, and GORT in English and Greek. These estimates indicate that Elision had the highest impact on Word Attack in English. In contrast, RAN-Digits had the highest impact on Word Attack in Greek. In addition, Orthographic Choice contributed to Word Attack in English but not in Greek. The

reading fluency measures were clearly affected most by RAN-Digits and Orthographic Choice, whose contributions were comparable across languages. Digit Span made a small contribution to the dependent variables in both languages. Taken together with the SEM results, we can conclude that the differences in the predictors of reading in the two languages are more obvious for word decoding than for reading fluency measures. The differences are also more apparent in the contributions of Elision and Orthographic Choice than in the contributions of Digit Span and RAN.

#### Discussion

The primary objective of this study was to compare the concurrent and longitudinal predictors of word decoding and reading fluency in children learning to read the orthographically consistent language of Greek with children learning to read the orthographically inconsistent language of English. Consistent with the PGST, phonological awareness, measured with Elision, contributed sig-

Table 4

Total Effects of Elision, RAN-Digits, Digit Span, and Orthographic Choice on Grade 2 Word Attack, TOWRE, and GORT

Measure	English <sup>a</sup>			Greek <sup>b</sup>		
	WAT	TOWRE	GORT	WAT	TOWRE	GORT
Elision	.414	.085	-.103	.173	-.002	-.055
RAN-Digits	-.143	-.395	.426	-.298	-.404	.343
Digit Span	.024	.044	-.096	.129	.070	-.130
OC	.367	.484	-.405	.076	.467	-.439

Note. WAT = Word Attack, TOWRE = Test of Word Reading Efficiency; GORT = Gray Oral Reading Test; RAN = Rapid Automatized Naming; OC = Orthographic Choice.

<sup>a</sup>  $N = 110$ . <sup>b</sup>  $N = 70$ .

nificantly to the prediction of English Word Attack in Grades 1 and 2 and in Grade 1 TOWRE. Further, the multigroup analyses indicated that phonological awareness predicted Word Attack and TOWRE better in English than in Greek. These results suggest that reading development in consistent orthographies imposes fewer demands on phonological awareness than in inconsistent orthographies (e.g., Landerl & Wimmer, 2000; Mayringer et al., 1998; Mann & Wimmer, 2002; Wesseling & Reitsma, 2000).

RAN-Digits predicted significantly Grade 1 Word Attack only in Greek, but the difference with the English model was not significant. When reading fluency measures were the dependent variables, RAN-Digits significantly contributed in both languages. Notably, the effect of RAN-Digits on Grade 1 TOWRE was larger in Greek than in English, but only in English did RAN-Digits have a direct effect in Grade 2 fluency after controlling for the autoregressors. These results are in line with previous studies showing that RAN is a significant predictor of reading fluency (e.g., Bowers, 1995; Georgiou et al., 2006; Katzir et al., 2006; Savage & Frederickson, 2005; Schatschneider et al., 2004) and likely exerts its influence early on in reading development (e.g., Compton, 2003; de Jong & van der Leij, 2002; Wagner et al., 1997).

When we repeated the SEM analyses with RAN-Colors in the place of RAN-Digits, RAN-Colors predicted significantly word decoding and reading fluency in Greek, but not in English. Constraining the regression weights to be equal across languages resulted in a nonsignificant change in the  $\chi^2$  value. The fundamental question of why RAN-Digits is a stronger predictor of reading ability than RAN-Colors remains to be resolved. Recently, Bowey and colleagues (2005) showed that the robust association between alphanumeric RAN tasks (Digit and Letter Naming) and reading within their fourth-grade sample was largely mediated by phonological processing and that, relative to nonalphanumeric RAN tasks (Color and Object Naming), alphanumeric RAN better assesses an underlying phonological processing ability that is common to word-reading ability. Correlations in Table 2 indicate that for English-speaking children, RAN-Digits did indeed show stronger correlations with Elision than RAN-Colors. However, the same correlational pattern was not evident in the Greek-speaking sample. As such, the results of this study do not provide clear support for either of the two main theoretical accounts explaining why RAN is related to reading (Bowers & Wolf, 1993; Torgesen et al., 1997). If RAN was measuring the speed of access to phonological representations, it should be more strongly related to reading in Greek. However, RAN-Digits predicted Word Attack similarly across languages. Likewise, if RAN was measuring the ability to form high quality orthographic representations, it should be more important for reading in English. However, RAN-Digits was a stronger predictor of Grade 1 TOWRE in Greek than in English. What RAN tasks measure and why they are related to reading are clearly questions that warrant further investigation.

The third component of phonological processing, phonological memory, contributed significantly only when predicting Grade 1 word decoding in Greek. This result may reflect the fact that the last few items in Word Attack in Greek were relatively long and retaining phonological information in short-term memory would have been helpful for successful blending and naming to take place. Nevertheless, the results of multigroup analysis indicated that the differences between the regression weights in the two languages were not statistically significant. Thus, our results are in

line with those reported recently by Caravolas and her colleagues (2005). In their study, general IQ and Digit Span were the only nonsignificant predictors of reading speed and spelling in English and Czech. Likewise, there are a number of studies conducted in various languages showing that phonological memory is only weakly correlated with reading ability (e.g., de Jong & van der Leij, 1999; Dufva, Niemi, & Voeten, 2001; Muter & Snowling, 1998; Parrila et al., 2004; Scarborough, 1998).

Orthographic processing was a robust predictor of word decoding in English and of reading fluency in both languages. This finding is particularly important in light of arguments regarding the preferred strategy in word decoding across languages that vary in orthographic consistency (Ziegler & Goswami, 2005, 2006). Several researchers have argued that children who are learning to read an orthographically consistent language rely heavily on grapheme-phoneme decoding strategies (e.g., Aro & Wimmer, 2003; Ellis et al., 2004; Goswami, 2002; Havelka & Rastle, 2005; Wimmer & Goswami, 1994). In such languages, phonological recoding can reliably operate at the smallest grain size because the mapping of graphemes onto phonemes is unambiguous. In contrast, children who are learning to read an orthographically inconsistent language must use a variety of decoding strategies (e.g., Decker, Simpson, Yates, & Locker, 2003; Goswami, 2002; Goswami, Porpodas, & Wheelwright, 1997; Seymour, 2005). Our decoding accuracy findings support these arguments. In English, the best predictors of word decoding were phonological awareness and orthographic processing. In Greek, the best predictor of word decoding was RAN. Orthographic processing did not contribute significantly. The significant effect of orthographic processing on Word Attack in English may also reflect that many of the Word Attack items in English have common letter patterns that can be decoded as orthographic units rather than letter by letter.

To the extent that our orthographic processing measure captured the use of sublexical orthographic units, the results show that readers in English rely on both small and large grain size units to decode (e.g., Goswami, 1999; Goswami et al., 1997; Ziegler & Goswami, 2005). Importantly, although orthographic processing did not predict word decoding in Greek, it did predict significantly reading fluency in both Grades 1 and 2 even when the autoregressor's effect was controlled. This finding suggests that Greek-speaking children made use of their orthographic knowledge only when there was a need for a speeded response.

Our findings provide an extension to PGST (Ziegler & Goswami, 2005) by providing an account of how grain size theory may be used to explain the rapid attainment of reading fluency in consistent orthographies. Recently, de Jong (2006) and Wimmer (2006) criticized PGST for its explicit focus on the development of reading accuracy. Specifically, Wimmer (2006) argued that "learning to read (as viewed in PGST) is more or less equated with acquisition of recoding accuracy" (p. 447) and went on to propose that if PGST postulates a developmental trend from relying on small grain sizes to relying on larger ones, then it could accommodate reading fluency attainments.

However, it may also be the case that, with development, speed of processing small grain size units becomes faster and this, per se, leads to better performance in fluency tasks. If children learning to read a consistent orthography receive positive feedback on effective use of phonological recoding in word identification, then they may rely on the same grain size for efficient reading fluency. This,

in turn, would result in word length effects. Indeed, Ziegler, Perry, Jacobs, and Braun (2001) demonstrated that German adult readers exhibited strong length effects for words and nonwords compared with their English-speaking Australian counterparts. Prompted by this finding, Ziegler et al. concluded that "orthographic consistency determines not only the relative contribution of orthographic versus phonological codes within a given orthography, but also the preferred grain size of units that are likely to be functional during reading" (p. 379). However, evidence from eye-movement studies and word naming in Italian (a consistent orthography) challenges this conclusion (e.g., Barca, Burani, Di Filippo, & Zoccolotti, 2006; Orsolini, Fanari, Tosi, De Nigris, & Carrieri, 2006; Zoccolotti et al., 2005). For example, Spinelli et al. (2005) reported that Italian fourth-grade children did not show a length effect for reading words from three to five letters. In adult readers the effect remained absent for up to eight letters. The absence of a length effect in high frequency words suggests that during the development of reading a serial sublexical word-reading strategy is supplemented by a more parallel lexical strategy.

A third possibility is that children in consistent orthographies demonstrate flexibility in using different grain size units. In timed conditions when a response must be generated quickly, large grain size units are likely to be employed, whereas in untimed conditions when maximum accuracy is desirable, phonological recoding is likely to be employed. Our findings support the latter explanation. In word decoding, Greek-speaking children relied on small grain size units as indicated by the significant effect of phonological awareness. In contrast, in reading fluency tasks, Greek-speaking children relied on large grain size units as indicated by the significant effect of orthographic processing. Thus, Greek-speaking children may adjust the grain size units to match the task demands. When no speed is required there is a reliance on phonological recoding and when a speeded response is needed, bigger grain size units are employed. Even in consistent orthographies, two routes of pronunciation assembly may be necessary to describe the reading process, but the activation of each route relies upon the demands of the reading task.

### Limitations

Some limitations of this study are worth mentioning. First, our findings can be generalized only to the languages under investigation and for the ages we tested. Greek has been used by many researchers as an example of a transparent orthography (e.g., Goswami et al., 1997; Seymour, Aro, & Erskine, 2003), but there are still objections to this conceptualization (e.g., Miles, 2000). Because the purpose of this study was to compare reading processes in a consistent orthography with an inconsistent orthography, using Greek might not have been as optimal a comparison language as Finnish or Turkish, which are considered nearly 100% consistent.

Second, the reading accuracy and fluency tasks were not strictly matched in the two languages. Greek and English belong to different families of languages and have different orthographic and phonological characteristics. For example, there is a large body of short single-syllable words in English, whereas there is only a small number of such words in Greek. Given the number of single-syllable words used in existing reading tests in English (e.g., WRMT-R; Woodcock, 1998), it was not possible to construct

word-reading tasks in Greek that would be strictly parallel in terms of length and word frequency to the English ones. On the other hand, using more multisyllabic words in English likely will not create an equal task because of significant differences in the syllable structures between Greek and English.

Third, we should acknowledge the whole-word nature of the orthographic processing task used in our study. Grain sizes bigger than graphemes but smaller than words should also be tested. A task such as Word Likeness in which individuals are asked to select the letter string that looks like a real word in English from a pair of pronounceable nonwords (e.g., *filk* - *filv*) should be used in future studies. Such studies would provide more convincing evidence that orthographic knowledge (lexical and sublexical) predicts reading differently in languages varying in orthographic consistency.

Fourth, similar to many previous studies (e.g., Holland et al., 2004; Leppänen et al., 2006; Parrila et al., 2004; Schatschneider et al., 2004), we did not include any measures of intelligence. Although frequently used, controlling for intelligence can also be ill-advised unless the relationship between the chosen general ability measure and other predictors is well understood. As pointed out by Parrila et al. (2004), an additional problem arises when intelligence is operationalized as a vocabulary measure that is likely differentially related to various phonological processing abilities (e.g., Avons, Wragg, Cupples, & Lovegrove, 1998; Metsala, 1999). Furthermore, other cross-linguistic studies have indicated that IQ does not contribute significantly to reading speed (e.g., Caravolas et al., 2005). Finally, we made sure that the children who participated in this study were able to understand and execute the instructions and that none of them had diagnosed developmental disabilities.

The last limitation concerns the use of observed variables instead of latent variables in the SEM analyses. When relationships among latent variables are examined, the relationships are free of measurement error because the error can be estimated and removed. On the other hand, SEM analyses using observed variables assume that the measures have perfect reliability coefficients, which clearly is not the case. Particularly, Digit Span in Greek had low reliability, which may have attenuated the correlations with the reading outcomes. However, the results for Digit Span were so similar for the English- and Greek-speaking sample that low reliability is unlikely to be a major issue.

### Conclusions

Our findings add to a small but growing body of research that directly compares children learning to read in two different languages and suggest that both phonological and orthographic processing skills are important in early reading acquisition. However, at least at the early stages of reading development, the effects of them are moderated by the characteristics of the language, a conclusion that is based on the differential effects of phonological awareness and orthographic processing on word decoding and reading fluency measures. Although some of the differences might be short-lived (see Table 4), our findings challenge Patel and colleagues' (2004) suggestion that "to the extent that alphabetic languages map orthography to phonology, the predictors of reading performance are likely to be universal" (p.794). In contrast, we argue that the orthography that children are learning to read is an

important factor that needs to be taken into account when models of reading development are being generalized across languages. By considering the differences between language systems, cross-linguistic studies can be a powerful tool in our attempt to understand both universal and language-specific processes involved in reading acquisition.

# Working Memory and Intelligence in Children: What Develops?

H. Lee Swanson  
University of California, Riverside

This study explored the contribution of the phonological and executive working memory (WM) systems to 205 (102 girls, 103 boys, 6 to 9 years old) elementary school children's fluid and crystallized intelligence. The results show that (a) a 3-factor structure (phonological short-term memory [STM], visual-spatial WM, and verbal WM) was comparable between age groups, (b) controlled attention and STM storage accounted for 67% of the age-related variance in WM, (c) effect sizes for direct paths from WM were substantially larger when predicting fluid intelligence than crystallized intelligence, and (d) the contribution of STM to intelligence was isolated to reading. The results suggest that the development of WM is distinct from STM, controlled attention plus storage accounted for age-related WM changes, and WM underlies age-related changes in both fluid and crystallized intelligence.

*Keywords:* working memory, short-term memory, phonological processing, executive processing

Working memory (WM) plays a critical role in learning during childhood, supported by studies demonstrating close links between measures of WM and measures of learning, achievement, and intelligence (see Gathercole, Lamont, & Alloway, 2006; Swanson & Siegel, 2001, for a review). WM has been referred to as a processing resource of limited capacity, involved in the preservation of information while simultaneously processing the same or other information (e.g., Baddeley, 2000; Engle, Tuholski, Laughlin, & Conway, 1999). Recent studies suggest that age-related performance of older children can be characterized as an ability to retain information in memory while simultaneously processing the same or other information when compared to younger children (e.g., Barrouillet & Camos, 2001; Conlin, Gathercole & Adams, 2005; Gavens & Barrouillet, 2004; Swanson, 1999). Age-related performance patterns are also observable in children on measures of fluid intelligence and skills related to measures of crystallized intelligence, such as reading and mathematics, as these areas of intelligence are considered to make large demands on WM capacities (e.g., Fry & Hale, 2000; Hitch, Towse, & Hutton, 2001; Siegel, 1994; Swanson, 1999). In these studies, WM has been viewed as distinct from short-term memory (STM). STM is viewed as involving situations where small amounts of material are held passively (i.e., minimal information is drawn from long-term memory to interpret the task, e.g., digits or word span tasks) and then reproduced in a sequential or untransformed fashion (e.g., Just & Carpenter, 1992).

## Distinction Between WM and STM

This study addressed three questions related to the development of WM in children. The first question addressed whether age-related changes in young children's WM are distinct from age-related changes in STM. An emerging consensus in the literature with adult participants is that WM and STM are distinct but highly related processes (e.g., see Heitz, Unsworth, & Engle, 2005, for a review). For example, Engle et al. (1999) found that STM and WM tasks loaded on two different factors (also see Cantor, Engle, & Hamilton, 1991; Conway, Cowan, Bunting, Theriault, & Minkoff, 2002, for similar findings). Although strong correlations emerged between the two factors ( $r = .70$ ), they found that a two-factor model fit the data better than a one-factor model. Further, they found that by statistically controlling the variance between WM and STM factors that the residual variance related to the WM factor was significantly correlated with measures of fluid intelligence (e.g., Raven Progressive Matrices Test [Raven, 1976] and the Cattell Culture Fair Test [Cattell, 1973]). That is, they found a strong link between the latent measures of WM, but not STM, to fluid intelligence. They interpreted their findings as suggesting that the residual variance related to the WM factor corresponded to controlled attention of the central executive system, and this system, in turn, was strongly correlated with measures of fluid intelligence.

The present study raises an important question as to whether STM and WM reflect two independent systems in children. One of the reasons for addressing this question is that STM and WM tasks have been found to load on the same factor in children. For example, Hutton and Towse (2001) found, via a principal-components analysis, that both WM and STM tasks loaded on the same factor for children 8 to 11 years old. Their results also showed that correlations related to WM and STM on measures of reading (.48 vs. .45), number skills (.33 vs. .38), and fluid intelligence (.35 vs. .36) were of the same magnitude (see Table 4), suggesting that WM and STM share the same construct (also see Cowan et al., 2003, for a similar finding). As stated by Hutton and Towse,

---

This article is based on a 3-year longitudinal study funded by U.S. Department of Education, Cognition and Student Learning (USDE R305H020055), Institute of Education Sciences awarded to H. Lee Swanson. I am indebted to Georgia Doukas, Diana Dowds, Rebecca Gregg, Krista Healy, Crystal Howard, James Lyons, Kelly Rosston, Olga Jerman, Xinhua Zheng, and Leilani Sáez for data collection and/or task development. Special appreciation is given to Bev Hedin, who directed and managed data collection and school schedules in the 2nd year of the project. This article does not necessarily reflect the views of the U.S. Department of Education or the school districts.

"It appears that what holds for WM in adults may not be equally true for children, and vice versa. The study highlights the value of taking account of children's online processing during WM tasks, and in so doing suggests that WM and STM may, at least in some circumstances, be rather equivalent." (p. 392)

These findings, however, contrast with Gathercole, Pickering, Ambridge, and Wearing (2004), who investigated the structure of WM in children ages 4 to 15 years. Their results supported a basic modular structure of WM that was consistent with a tripartite adult-based model that includes phonological STM, executive processing, and the visual-spatial sketchpad.<sup>1</sup> However, it was unclear from Gathercole et al.'s (2004) results whether the processes that contributed to these structures were distinct. For example, the average factor correlation between measures of STM (phonological loop) and executive processing was .80 (see p. 186). In addition, the magnitude of this correlation increased across ages suggesting that the factor structure was less distinct for the older than younger participants. The authors indicated that the close association between the factors associated with the phonological STM and the executive component of WM was because "the central executive's identification was based on tasks that are constrained by phonological loop capacity" (p. 188). Given these findings, further work is necessary to determine whether children's STM is distinct from WM.

### Controlled Attention Versus Storage

The second question this study addresses is whether controlled attention and/or STM play the major role in age-related changes in children's WM span. In elaborating the distinction between STM and WM in children, Cowan (1995) emphasized the role of attentional processing in children's WM development. WM is described as a subset of items of information that are stored in STM and submitted to "controlled attentional" processing. *Controlled attention* is defined as the capacity to maintain and hold relevant information in the face of interference or distraction and is measured by partialing out the influence of STM from WM performance (Engle et al., 1999). The majority of measures used to tap some aspects of controlled attention involved inhibition (Rosen & Engle, 1997). Although controlled attention has been argued as a component of WM, the majority of research suggests that storage and speed underlie WM span. For example, McCabe and Hartman (2003) found that the locus of age effects on WM tasks for younger and older adults were due to an ability to store verbal material in STM and processing speed. Likewise, Bayliss, Jarrold, Baddeley, Gunn, and Leigh (2005) found with children (6 to 10 years of age) that processing speed and storage contributed to WM span. Thus, the role of controlled attention as underling children's WM span needs to be investigated further.

### Crystallized Versus Fluid intelligence

The third question addresses whether the influence of WM is primarily directed to fluid intelligence and/or crystallized intelligence. Fluid intelligence is typically assessed on standardized measures that tap reasoning, thinking, or the ability to acquire new knowledge, whereas crystallized intelligence is assessed on measures that tap what has been learned in a particular domain (e.g., reading and math; Cattell, 1971; Horn, 1980; Horn & Noll, 1997). *Fluid intelligence* is defined as the ability to reason (e.g., induce

abstract relations) under novel conditions, whereas *crystallized intelligence* is defined as academic achievement or cultural knowledge based on already learned knowledge (Cattell, 1971; also see Haavisto & Lehto, 2005, for an extensive review). Because verbal and numerical abilities are known to load on crystallized intelligence (Cattell, 1971), for this study I use reading and math tasks to reflect the verbal and numerical domains of crystallized intelligence, respectively.

I assumed that WM is essential for the mental activities basic to children's intelligence. For example, age-related changes in WM, with its capacity constraints, may provide an important foundation on intelligence measures related to children's reasoning (e.g., Fry & Hale, 2000), reading (e.g., Siegel, 1994), and mathematics (e.g., Geary, Hoard, & Hamson, 1999). The available evidence indicates that WM is an important part of the cognitive basis of intelligence (e.g., Case, 1992; Schweizer & Koch, 2002). However, because a part of WM distinguishes between STM and controlled attention, the question arises as to whether WM as an attentional mechanism or WM as storage (STM) is an especially important source of age-related differences in children's intelligence. Some authors emphasize the phonological storage aspect of WM (e.g., phonological loop) on measures of crystallized intelligence (i.e., reading; e.g., Shankweiler & Crain, 1986). Others suggest that efficiency of the executive system contributes to the relationship between WM and fluid intelligence (e.g., Case, 1992). Thus, the connecting mechanisms between WM and the two types of intelligence are unclear. It is possible that the executive system of WM (which manages a number of goals, representations, and procedures for problem solving, which requires controlled attention) acts as the critical WM factor for fluid intelligence tasks (e.g., Oberauer, Süß, Wilhelm, & Wittman, 2003), whereas the storage component of WM (accessing previously learned information) acts as the critical WM mechanism on crystallized tasks (e.g., see Hambrick & Engle, 2002, for the discussion on the role of domain-specific knowledge and WM). That is, WM is related to crystallized intelligence to the extent that WM reflects a resource that can be used to activate preexisting stored information and maintain that activation during the performance of some task. In addition, keeping and maintaining task-relevant information and inhibiting may be related to both fluid and crystallized intelligence. Thus, an investigation of the components (i.e., STM vs. controlled attention) of WM most related to children's intelligence is further warranted.

<sup>1</sup> In this model, Baddeley (1986; Baddeley & Logie, 1999) described WM as a limited capacity central executive system that interacts with a set of two passive store systems used for temporary storage of different classes of information: the speech-based phonological loop and the visual sketchpad. The phonological loop is responsible for the temporary storage of verbal information; items are held within a phonological store of limited duration, and the items are maintained within the store via the process of articulation. The visual sketchpad is responsible for the storage of visual-spatial information over brief periods and plays a key role in the generation and manipulation of mental images. Both storage systems are in direct contact with the central executive system. The central executive system is considered to be primarily responsible for coordinating activity within the cognitive system, but also devotes some of its resources to increasing the amount of information that can be held in the two subsystems (Baddeley & Logie, 1999). This model has been revised to include an episodic buffer (Baddeley, 2000), but support for the tripartite model has been found across various age groups (Gathercole et al., 2004).

Unfortunately, very little research has examined whether the processes that mediate the correlations between WM and crystallized intelligence measures are the same as those that mediate the correlations between WM and fluid intelligence measures. There are some studies suggesting that fluid and crystallized intelligence are more closely related in younger than older children because the school curriculum tends to standardize student's knowledge base (Schweizer & Koch, 2002). Thus, one may expect the magnitude of the correlations between WM and fluid intelligence and WM and crystallized intelligence to be more similar in younger than older children. There is some evidence from functional magnetic resonance imaging studies suggesting that development in fluid intelligence is related to the frontal lobe development (e.g., see Kane, 2005, for a review), whereas age-related changes on crystallized measures, such as the area of reading, are related to the maturation of temporal and parietal sections of the brain (e.g., Paulesu et al., 2001). Likewise, different components of WM have been related to the development of different regions of the brain. For example, STM (phonological loop) has been associated with the left temporal parietal region (Baddeley, 1986), whereas the executive system of WM is associated with the frontal lobes (T. D. Wagner & Smith, 2003; also see Kane, 2005, for a review). Thus, it seems reasonable from these studies that different processes as a function of age may mediate the influence of WM on different intelligence measures.

There is some evidence that the importance of WM in predicting intelligence varies with age. For example, the links between WM and fluid intelligence established in adults have not generalized to children. For example, Bayliss, Jarrold, Gunn, and Baddeley (2003) found with children (7 to 9 years old) that the residual variance between the two factors (WM and STM) was not linked to fluid intelligence (Raven Progressive Matrices Test) but was linked to measures of crystallized intelligence (reading and math). That is, in contrast to Engle et al.'s (1999) work with adult samples, no significant relationship emerged between children's complex span performance (WM) and performance on the Raven Progressive Matrices Test. Rather Bayliss et al. (2003) found that measures of processing efficiency (reaction time) and STM storage predicted performance on measures of reading and math, but not fluid intelligence.

### Phonological Loop Model

In summary, this study addresses questions as to whether WM and STM operate as distinct systems, whether controlled attention and/or storage mediate age-related changes in WM, and whether WM has more direct influence on one form of intelligence than another. To address these questions, I consider the contribution of the phonological and executive processes in accounting for age-related differences in WM and intelligence. Two models are considered. The first model hypothesizes that age-related differences in WM are strongly related to the phonological loop (STM).<sup>2</sup> The model assumes that because younger children's phonological system is more developed than their executive system when compared to older children, WM and STM are the same in younger children. Thus, WM and STM represent a single factor in young children. In contrast, STM and WM are distinct factors in older children. Indirect evidence for this assumption comes from studies linking the phonological system to a number of activities (e.g., language, reading) during early childhood years (e.g., Baddeley,

Gathercole, & Papagno, 1998), and therefore executive processing activities attributed to the WM system may develop much later in children than the phonological loop. There is some literature suggesting that tasks related to the phonological loop (i.e., STM) and executive system are not clearly distinguishable in young children (Gathercole et al., 2004). This lack of distinguishability may reflect the fact that the phonological system plays a more dominant role in WM performance than processes commonly attributed to the executive system (e.g., controlled attention).

I extend this research by investigating the processes that mediate the influence of WM on children's intelligence. A simple version of the above hypothesis states that younger children are less efficient at accessing and storing phonological information than older children and that such reduced processing on the children's part underlies children's lower performance on WM and intelligence measures. For example, one of the possible reasons WM span increases as a function of age is because older children store more information, which in turn is due to their ability to name items more rapidly than younger children (Henry & Millar, 1993; Hulme, Thomson, Muir, & Lawrence, 1984). Rapid naming is assumed to enhance the effectiveness of subvocal rehearsal processes and hence reduce the decay of memory items in the phonological store prior to output (e.g., Henry & Millar, 1993; Hulme et al., 1984; see Gathercole, 1998, for review). Naming speed has been interpreted as a measure of how quickly items can be encoded and rehearsed within the phonological loop (e.g., McDougall, Hulme, Ellis, & Monk, 1994). Another possible reason for age-related changes in WM is that older children are more aware of (or knowledgeable about) the sound structures in language than younger children. Several studies show that measures of verbal STM and phonological knowledge are strongly associated (e.g., see Alloway, Gathercole, Willis, & Adams, 2004, pp. 87–88, for review), and therefore greater phonological processing abilities are related to higher STM scores because they tap a common processing substrate (e.g., Griffiths & Snowling, 2002). There are clear expectations in this model. The influence of WM on measures of fluid and crystallized intelligence in children follows automatically with age-related improvements in the phonological loop.

### Executive Process Model

In contrast to the above model, the second model views age-related changes in the executive component of WM (i.e., controlled attention) as well as storage as underlying children's WM performance. That is, age-related changes in WM depend on both the phonological loop (STM) and the executive system. This model assumes there is unique variance related to both the executive and the phonological system of WM that contribute to children's intelligence. The executive component of interest is

<sup>2</sup> Previous research has already established links between the phonological system and STM (e.g., see Alloway, Gathercole, Willis, & Adams, 2004, for a review). For example, studies that have compared older and younger children have suggested that STM measures capture the utilization and/or operation of the phonological loop (see Gathercole, 1998; Gathercole & Baddeley, 1993, for a comprehensive review). The phonological loop has been referred to as STM (e.g., Baddeley, 1986; Baddeley, Lewis, & Vallar, 1984), because it involves two major components discussed in the STM literature: a speech-based phonological input store and a rehearsal process (see Baddeley, 1986, for review).

controlled attention.<sup>3</sup> Thus, in contrast to the aforementioned hypothesis that suggests phonological processes play a more dominant role in the mediating effects of WM on children's intelligence, this model assumes that executive processes (i.e., controlled attention) also play a major role in mediating both fluid and crystallized intelligence in children. Thus, there are clear expectations for this second model. The influence of WM on measures of fluid and crystallized intelligence in children follows automatically with improvements in controlled attention.

How might controlled attention contribute to age-related and individual differences in fluid and crystallized intelligence? To address this question, I administered two tasks that I assume are related to controlled attention: fluency and random generation. These tasks have been shown to tap two aspects of controlled attention processing: inhibition of competing responses during a controlled search for items (e.g., Rosen & Engle, 1997) and the filtering of rote or habitual responses (Towse, 1998). For example, the fluency task requires individuals to spontaneously generate words in response to a category cue (e.g., generate animal names) or specific letter cue (generate words that begin with the letter *b*). These tasks have been associated with the executive functions related to the controlled search for words (e.g., see Rende, Ramberger, & Miyake, 2002, for review). That is, participants are directed to activate needed information (animal names) while inhibiting the repetition of exemplars. In the random generation procedure, on the other hand, participants are asked to keep track of the number of times items have been generated and to inhibit well-known sequences such as "1, 2, 3, 4" or "a, b, c, d." Baddeley (1986) indicated that during random generation, the central executive acts as a filtering device, screening out automatically generated (and therefore nonrandom) responses. This task differs somewhat from the fluency measure because participants must inhibit rote or habitual responses (saying the letters of the alphabet in order) in order to quickly complete the task. Thus, during random generation the central executive acts as a rate-limited filtering device that filters out habitual responses (see Towse, 1998, for a review of this measure). Although not pure measures of inhibition, both tasks do require active suppression in order to perform the task efficiently.

### Purpose of Study

In summary, this study had two purposes. The first was to determine whether two independent memory systems related to STM and WM provide an adequate representation of transient memory in both younger and older children. The second purpose was to determine the processes that mediate age-related changes in the phonological loop and/or executive system and whether these same processes mediate the relationship between WM and intelligence. Because I assumed that age-related changes in WM may be due to age-related changes in children's phonological system, 8- and 9-year-old children's performance was compared with 6- and 7-year-old children's performance on measures of WM and STM. Engle et al. (1999) suggested that STM and WM might not be distinguishable in young children whose rehearsal processes are unstable. Further, several studies show weak to moderate correlations between memory span and articulation rates in children 7 years of age and below (see Gathercole, 1998, pp. 6–7, for review). This occurs because younger children's time-based strategies (i.e., rehearsal) are unstable (Gathercole, 1998). Thus, I se-

lected age levels where memory strategies are stable (8- and 9-year-olds) versus unstable (6- and 7-year olds) to better assess the processes that mediate the relationship between WM, STM, and intelligence.

### Predictions

Three predictions were tested in this study. First, a phonological loop and executive processing model provides an adequate representation of the data. If WM and STM are indeed distinct constructs in children, then an STM and a general WM factor should fit the data better than a one-factor solution. I also tested whether the separate phonological and executive factor structure holds for the two age groups.

Second, age-related changes in children's WM are mediated by both STM and controlled attention. Thus, both measures of STM and controlled attention predict age-related changes in WM.

Finally, WM predicts age-related increases in both fluid and crystallized intelligence. Likewise, WM draws from age-related increases in controlled attention and storage when predicting performance on fluid and crystallized measures of intelligence.

### Method

#### Participants

Two hundred and five children who were 6 to 9 years of age from a southern California public school district and private school district participated in this study. Final selection was related to parent approval for participation. Of the 205 participants, 102 were girls and 103 were boys. Children were divided into younger (ages 6 and 7,  $n = 98$ ) and older age groups (ages 8 and 9,  $n = 107$ ). Gender representation was not significantly different between the two age groups,  $\chi^2(1) = .0045, p > .05$ . Ethnic representation of the sample was 85 Anglo, 89 Hispanic, 18 African American, 9 Asian, and 4 other (e.g., Native American, Vietnamese). No significant differences emerged between the two age groups in terms of ethnicity,  $\chi^2(5) = 5.87, p > .05$ . The mean socioeconomic

<sup>3</sup> Some clarification between executive processing and controlled attention is necessary. The central executive is involved in the control and regulation of the WM system. Several cognitive activities have been assigned to the central executive (e.g., see Miyake, Friedman, Emerson, Witzki, & Howerter, 2000, for a review), such as controlling subsidiary memory systems, control of encoding and retrieval strategies, attention switching during manipulation of material held in the verbal and visual-spatial systems, suppressing irrelevant information, accessing information for long-term memory, and so on (e.g., Baddeley, 1996; Miyake et al., 2000; Oberauer et al., 2003). According to Baddeley and Logie (1999), the executive system coordinates the two subordinate systems (phonological loop and visual-spatial sketchpad), focusing and switching attention, in addition to activating representations within long-term memory. Thus, several activities could be assigned to the central executive. Some of these activities have been reduced to three functions: (a) updating and monitoring of working memory representations, (b) inhibition of dominant or prepotent responses, and (c) shifting between mental sets (Miyake et al., 2000). In this study, I focus on one aspect of the executive system: controlled attention. Controlled attention is operationally defined as the residual variance left in WM when STM has been partialled from the analysis (Engle et al., 1999). I assumed that this residual variance (i.e., controlled processing) is reflected in activities that involve the inhibition of competing information from the targeted information.

status of the sample was primarily middle to upper middle class on the basis of parent education or occupation. Means and standard deviations for the selection variables used in this study are shown in Table 1.

### Tasks and Materials

The battery of group and individually administered tasks is described below. Experimental tasks are described in more detail than published and norm referenced tasks. All experimental tasks included two practice trials.

### Measures of Fluid and Crystallized Intelligence

**Fluid intelligence.** Fluid intelligence was assessed by the Raven Progressive Matrices Test (Raven, 1976). Children were given a booklet with patterns displayed on each page, each pattern revealing a missing piece. For each pattern, four possible replacement pattern pieces were displayed. Children were required to circle the replacement piece that best completed the patterns. After

the introduction of the first matrix, children completed their booklets at their own pace. Patterns progressively increased in difficulty. The dependent measure (range = 0–36) was the number of problems solved correctly.

**Arithmetic computation.** The Arithmetic subtest from the Wide Range Achievement Test—Third Edition (WRAT-III; Wilkinson, 1993) was administered. The dependent measure was the number of problems correct, which yielded a standard score.

**Reading.** Reading was assessed by the Word Recognition subtest of the WRAT-III. The task provided a list of words of increasing difficulty. The child's task was to read the words until 10 errors occurred. The dependent measure was the number of words read correctly.

### Phonological Knowledge Measures

Because the phonological measures are commonly used and derived from published standardized measures (i.e., Woodcock Reading Mastery Test—Revised [Woodcock, 1998], Wechsler In-

\* *p* < .05. \*\* *p* < .01.

telligence Scale for Children—Third Edition [Psychological Corporation, 1991], Comprehensive Test of Phonological Processing (CTOPP; R. Wagner, Torgesen, & Rashotte, 2000), I only briefly describe these tasks.

*Pseudoword reading task.* The Pseudoword subtest was administered from the Test of Word Reading Efficiency (R. Wagner & Torgesen, 1999). The subtest required oral reading of a list of 120 real words or pseudowords of increasing difficulty. Children were given 45 s to say aloud as many words as possible from a list of nonwords. The nonwords followed regular spelling patterns, requiring children to quickly decipher pronunciations based on their existing knowledge of phonology. The dependent measures for both subtests were the number of words said correctly in 45 s.

*Elision or phonological deletion.* The Elision subtest from the CTOPP (R. Wagner et al., 2000) was administered. The Elision subtest measures the ability to parse and synthesize phonemes. The child was asked to say a word and to say what word is left if part of the word is deleted. There are four practice items and 15 test items. The dependent measure was the number of items said correctly.

### Naming Speed

*Digit naming speed.* The administration procedures followed those specified in the manual of the CTOPP (R. Wagner et al., 2000). For this task, the examiner presented participants with an array of 36 digits. Participants were required to name the digits as quickly as possible for each of two stimulus arrays containing 36 items, for a total of 72 items. The task administrator used a stopwatch to time participants on speed of naming. The dependent measure was the total time to name both arrays of numbers. The correlation between array Form A and B was .91.

*Letter naming speed.* The administration procedures followed those specified in the CTOPP (R. Wagner et al., 2000), including the presentation of practice trials. The manual reports correlations between parallel forms ranging from .80 to .93. For this task, the examiner presented participants with an array of 36 letters. Participants were required to name the letters as quickly as possible for each of two stimulus arrays containing 36 letters, for a total of 72 letters. The task administrator used a stopwatch to time participants on speed of naming. The dependent measure was the total time to name both arrays of letters. The correlation between array Form A and B was .90.

### Inhibition

Verbal fluency tasks required individuals to spontaneously generate words for 60 s, in response to a category cue (e.g., generate animal names) or specific letter cue (generate words that begin with the letter *b*). These tasks have been associated with frontal lobe function, and individual differences have been linked to executive functions (e.g., controlled search for words; e.g., see Rende, Ramsberger, & Miyake, 2002, for review). In this study, fluency tasks were presumed to reflect monitoring of responses to avoid repetitions during the generation of multiple response alternatives. Two verbal fluency tasks were administered and are described below.<sup>4</sup>

*Semantic fluency.* The experimental measure was adapted from Harrison, Buxton, Husain, and Wise (2000). Children were given 60 s to generate as many names of animals as possible.

Children were told, "I want to see how many animals you can name. Try not to repeat yourself. Don't say pet names. Keep going until I tell you to 'stop.' Ready, begin." Repetitions were deleted from the analysis. The dependent measure was the number of words correctly stated within 60 s.

*Phonological fluency.* This experimental measure was also adapted from Harrison et al. (2000). Children were given 60 s to generate as many words as possible beginning with the letter *b*. Children were told,

I want to see how many words you can say that begin with a certain letter. Do not say proper nouns or numbers or the same word with different endings and try not to repeat yourself. Keep naming words that start with the letter until I say "stop." Speak clearly and loudly enough so that I can hear the word you are saying. Do you understand? The letter is *b*. Begin.

Repetitions, proper name errors, as well as contravention of the stem repetition were deleted from the analysis. The dependent measure was the number of words correctly stated in 60 s.

*Sequential and random generation of letters and numbers.* The random generation task has been well articulated in the literature (e.g., Baddeley, 1996; Towse, 1998). The task measures controlled attention because participants are required to actively monitor candidate responses and suppress responses that would lead to well-learned sequences, such as 1-2-3-4 or a-b-c-d (Baddeley, 1996). Because this task has been primarily used with adult samples who have quicker access to letters and numbers, it was modified for the age group in this study. Each child was asked to write as quickly as possible numbers (or letters) in sequential order to establish a baseline of their ability to quickly access learned information. Children were then asked to quickly write numbers (or letters) in a random nonsystematic order. For example, for the number section, children were first asked to write numbers from 0 to 9 in order (i.e., 1, 2, 3, 4) and repeatedly as quickly as possible in a 30-s period. They were then asked to write numbers as quickly as possible "out of order" within a 30-s period. Two scores were calculated: speeded order retrieval and nonorder generation. For the speeded retrieval score, the total number of numbers or letters written in correct order was scored. The measure of random generation was calculated as the number of letters or numbers out of sequential order. As a measure of inhibition, random generation scores (corrected for redundancy and order) were subtracted from the speed retrieval (nonrandom generation) score. The scores were combined because a preliminary analysis of the data showed a tradeoff between speed and accuracy. Thus, it was assumed that high difference scores reflected a tradeoff between accuracy and speed.

### STM Measures

Three measures of STM were administered: Forward Digit Span, Word Span, and Pseudoword Span. The Forward Digit Span

<sup>4</sup> I assumed that the switching between the semantic retrieval aspect of the fluency task taps attentional control and the ability to inhibit previous responses (e.g., Rende et al., 2002; Rosen & Engle, 1997). As indicated by one reviewer, however, multiple processes can contribute to fluency tasks besides inhibition, including strategic initiation, sustain effort in conducting searches, and associative-semantic retrieval processes. Thus, I agree with the reviewer that I do not have a pure measure of inhibition.

subtest from the Wechsler Intelligence Scale for Children—Third Edition was administered. The Forward Digit Span task required participants to recall and repeat in order sets of digits that were spoken by the examiner and that increased in number. The Word Span and Pseudoword Span tasks were presented in the same manner as the Forward Digit Span measure. The Word Span task was previously used by Swanson, Ashbaker, and Lee (1996). The word stimuli are one- to two-syllable high-frequency words. Children are read lists of common but unrelated nouns and then are asked to recall the words. Word lists gradually increased in set size, from a minimum of two words to a maximum of eight. The Pseudoword Span task (Swanson & Berninger, 1995) used strings of nonsense words (one syllable long), which are presented one at a time in sets of 2–6 nonwords (e.g., *zeb, vab; sme, pru, tri*). The dependent measure for all STM measures was the highest set of items retrieved in the correct serial order (scores ranged from 0 to 7).

### WM Measures

The WM tasks in this study required children to hold increasingly complex information in memory while responding to a question about the task. The questions served as distracters to item recall because they reflected the recognition of targeted and closely related nontargeted items. A question was asked for each set of items, and the tasks were discontinued if the question was answered incorrectly or if all items within a set could not be remembered. Thus, WM span reflected a holding of some information (item storage) during the processing of other information (correct responses to questions). Consistent with Daneman and Carpenter's (1980) seminal WM measure, the processing of information was assessed by asking participants simple questions about the to-be-remembered material, whereas storage was assessed by accuracy of item retrieval. The question required a simple recognition of new and old information and was analogous to the yes/no response feature of Daneman and Carpenter's task. It is important to note, however, that in my tasks the difficulty of the processing question remained constant within task conditions, thereby allowing the source of individual differences to reflect increased storage demands. Further, the questions focused on the discrimination of items (old and new information) rather than deeper levels of processing such as mathematical computations (e.g., Towse, Hitch, & Hutton, 1998). A previous study with a different sample established the reliability and the construct validity of the measures with the Daneman and Carpenter measure (Swanson, 1996, 1999). For this study, three WM tasks were selected from a standardized battery of 11 WM tasks because of their high construct validity and reliability (see Swanson, 1992). The complete description of administration and scoring of the tasks are reported in Swanson (1995). A children's adaptation of the Daneman and Carpenter measure (Swanson, 1992; Swanson & Ashbaker, 2000) was also administered. Each WM task was scored by the highest set of items achieved when the process question was correct. However, partial credit (.50) was given if the process question was correct but not all items in the array were recalled perfectly. For example, if a child correctly recalled Set 1 but missed recalling perfectly the next highest set (Set 2) but got the process question correct, his or her WM score was 1.5. For all WM and STM tasks, children were presented two practice trials. After successful completion of the

practice trials, children were provided sets of items that increased in difficulty. Task descriptions follow.

*Mapping and directions.* This task required the child to remember a sequence of directions on a map (Swanson, 1992, 1995). The experimenter presented a street map with dots connected by lines; arrows illustrated the direction a bicycle would go to follow this route through the city. The dots represented stoplights, while lines and arrows mapped the route through the city. The child was allowed 10 s to study the map. After the map was removed, the child was asked a process question. The process question asked the children to indicate whether a stop line was in a particular column. The child was then presented a blank matrix on which to draw the street directions (lines and arrows) and stop lights (dots). Difficulty ranged on this subtest from 4 dots to 19 dots. The dependent measure was the highest set of a correctly drawn map (range = 0–9) in which the process question was answered correctly.

*Visual matrix task.* The purpose of this task was to assess the ability of participants to remember visual sequences within a matrix (Swanson, 1992, 1995). In contrast to the standardization procedures (Swanson, 1995), the visual matrix task was administered in small groups. An overhead projector was used to display stimuli to groups of children instead of individually by use of the examiner's manual. This change in format required students to circle their answer to the process question, rather than to verbally respond. Otherwise, the task was administered as per the manual instructions. Participants were presented a series of dots in a matrix and were allowed 5 s to study the matrix. After the matrix was removed, the child was asked a process question. The process question asked the children to indicate whether there were dots in a particular column. To ensure the understanding of columns prior to testing, participants are shown the first column location and practice finding it on blank matrices. In addition, for each test item the experimenter pointed to the first column on a blank matrix (a grid with no dots) as a reminder of first column location. After answering the discriminating question (by circling *y* for yes or *n* for no), students were asked to draw the dots they remembered seeing in the corresponding boxes of their blank matrix response booklets. The task difficulty ranged from a matrix of 4 squares and 2 dots to a matrix of 45 squares and 12 dots. The dependent measure was the highest set recalled correctly (range of 0 to 11) in which the process question was answered correctly.

*Conceptual Span.* The purpose of this task was to assess the participant's ability to organize sequences of words into abstract categories (Swanson, 1992, 1995). The participant was presented a set of words (one every 2 s), asked a discrimination question, and then asked to recall the words that go together. For example, a set might include the following words: *shirt, saw, pants, hammer, shoes, nails*. Participants were directed to retrieve the words that go together (i.e., *shirt, pants, and shoes; saw, hammer, and nails*). The process or discrimination question asked the child to choose whether a targeted word or nontargeted word was in the list of words. Thus, the task required participants to transform information encoded serially into categories during the retrieval phase. The range of set difficulty was two categories of two words to five categories of four words. The dependent measure was the highest set recalled correctly (range of 0 to 8) in which the process question was answered correctly.

*Listening Sentence Span.* The children's adaptation (Swanson, 1992) of Daneman and Carpenter's (1980) Sentence Span task was administered. The construction of, and pattern of results associated

with, the two measures are comparable. The only difference was that each sentence was read to the child with a 5-s pause that indicated the end of a sentence. The original Sentence Span measure was used with university students, whereas the current measure uses simpler sentences and reading vocabulary. WM capacity was defined as the largest group of ending words recalled. The mean sentence reading level (based on a Fleisher reading index) was approximately 3.8. The dependent measure was the highest set recalled correctly (range of 0 to 8) in which the process question was answered correctly.

### Reliability

The reliability of the measures was computed for this sample. Because the subsequent analysis relied on raw scores for analysis, the reliability of all raw score measures were calculated. Further, because reliability is inflated across a large age range, I calculated the reliabilities within each age group. As shown in Table 1, Kuder–Richardson Formula 20 scores varied, with the majority of coefficients hovering around .70. Further, the majority of reliability coefficients are within an acceptable range for basic research (around .70; see Nunnally & Bernstein, 1994, pp. 264–265, for discussion).

### Procedure

Three doctoral-level graduate students trained in test administration tested all participants in their schools. Two sessions of approximately 45–60 min each were required for small group test administration and one session of 45–60 min for individual test administration. During the group testing session, data were obtained from the Raven Progressive Matrices Test and the WRAT-III. The remaining tasks were administered individually. Test administration was counterbalanced to control for order effects. Task order was random across participants within each test administrator.

## Results

The means and standard deviations for measures of fluid intelligence, crystallized intelligence (reading, arithmetic calculation), phonological knowledge, naming speed, sequential and random generation, fluency, STM, and WM are shown in Table 1. Table 1 also reports the reliability of each measure and the univariates and effect sizes ( $\eta^2$ ) for each comparison. An  $\eta^2$  of .13, .05, and .02 corresponded to Cohen's  $d$  of .80, .50, and .20, respectively. The analyses and results were divided into two sections. The first section focused on age differences. The second section focused on correlations between STM and WM in the complete sample. This approach allowed us to study the entire range of scores in WM. I used a path analysis to test whether controlled attention (inhibition in this case) and/or storage (STM in this case) predicted age-related changes in WM. Hierarchical regression models were computed to determine the mediating role of WM on age-related changes in fluid and crystallized intelligence.

### Age Comparisons

A series of multivariate analyses of covariances were conducted to examine age-related differences in raw scores for accuracy or span for (a) fluid and crystallized intelligence (Raven,

arithmetic calculation, word recognition), (b) STM/WM, (c) naming speed/random generation, and (d) and phonological knowledge/fluency. The univariates are shown in Table 1. Alpha was set to .05 unless otherwise specified.

A significant multivariate main effect emerged for age on measures of crystallized and fluid intelligence, Wilks's  $\Lambda = .27$ ,  $F(3, 201) = 180.66$ ,  $p < .0001$ ; STM/WM, Wilks's  $\Lambda = .70$ ,  $F(7, 197) = 12.02$ ,  $p < .0001$ ; naming speed/phonological knowledge, Wilks's  $\Lambda = .59$ ,  $F(4, 200) = 33.80$ ,  $p < .0001$ ; and random generation/fluency, Wilks's  $\Lambda = .49$ ,  $F(4, 200) = 50.75$ ,  $p < .0001$ . Also shown are the significant effects related to difference scores from the random generation task. As expected, all univariates were significantly in favor of older children when compared to younger children. In general, the results clearly show that older children outperformed younger children across measures of fluid and crystallized intelligence, naming speed/controlled attention, STM/WM, and phonological knowledge.

### Correlation/Confirmatory Factor Analysis

Prior to my analysis of various processes assumed to underlie age-related changes in STM and WM performance, I investigated the correlation structure of WM and STM tasks for the total sample. The intercorrelations among the memory measures as well as process and criterion measures of the total sample ( $N = 205$ ) are shown in Table 2.<sup>5</sup> One finding worth noting was that the magnitude of the correlations within verbal WM measures (listening span and conceptual span,  $r = .62$ ) and visual spatial measures (mapping and visual matrix,  $r = .41$ ) was higher than between verbal and visual spatial measures ( $r$ s ranged from .11 to .30). This finding suggests that the memory tasks captured a diversity of memory operations.

*Confirmatory analysis.* Our hypothesis was that the structure of the memory measures, as reflected in Baddeley and Logie (1999), reflected three factors: phonological loop, visual–spatial sketchpad, and executive processing. In order to test this hypothesis, I first ran a confirmatory factor analysis with all the memory measures loading one factor. I then ran a second model with the WM tasks (mapping/direction, visual matrix, listening span, conceptual span) loading on one factor and the three STM tasks (forward digit, pseudoword, word span) on a separate factor. I then ran a third model with the two visual–spatial WM tasks (mapping/direction, visual matrix) on one factor, the two verbal WM tasks on a second factor (listening span, conceptual span), and the three STM tasks on a third factor. The fit statistics for the three models are shown in Table 3. Data were analyzed using the EQS 6.1

<sup>5</sup> Prior to testing my hypothesis, normalcy of the data was considered. As shown in Table 2, all memory measures meet standard criteria for univariate normality (Kline, 1998) with skewness for all measures less than 3 and kurtosis less than 4. Univariate outliers were defined as cases more than 3.5 standard deviations from the means. Multivariate outliers were examined by calculating Mahalanobis'  $d^2$ . None of the cases related to memory performance were deemed outliers. The data were also checked for multicollinearity. Except for rapid naming speed between letters and numbers, none of the zero-order correlations were above .80. One means to handle multicollinearity (as with the rapid naming measures) is to combine the scores into a latent measure, which occurs in the subsequent analysis. Overall, the zero-order correlations indicated that multicollinearity was not a problem with the memory data at the measurement level (Kline, 1998).

Note. NNFI = Bentler-Bonett nonnormed fit index; CFI = comparative fit index; RMSEA = root-mean-square error of approximation.

<sup>a</sup> Partial invariance removed the constraint that Visual Matrix loaded on the same factor for both age groups.

(Bentler, 2006), and the models tested were covariance structure models.

The chi-square statistic included in Table 3 provided a test of the null hypothesis that the model fits the data. If the model provided a good fit, the chi-square will be relatively small and corresponding *p* values will be relatively large. However, the chi-square is found to be significant even if the model is a good fit (Bentler & Wu, 1995). Therefore, researchers seek a small chi-square rather than a nonsignificant chi-square. Several studies recommend the nonnormed fit index (NNFI; Bentler & Bonnet, 1980) and the comparative fit index (CFI; Bentler & Wu, 1995) as overall goodness-of-fit indices. These indices are less likely to produce biased estimates in small samples. Values at .90 and over on the NNFI and CFI indicated an acceptable fit. The root-mean-square error of approximation measured the average residual correlation (Jöreskog & Sörbom, 1984). Small values (e.g., .10 or less) reflected a good fit.

As shown in Table 3, all the fit indices indicated that the three-factor model was a better fit to the data than the one- or two-factor model. A chi-square difference test indicated that the three-factor model did indeed fit the data significantly better than the two-factor model,  $\Delta\chi^2(1) = 64.43, p < .001$ . The three-factor model is shown in Figure 1 (top panel). Although the results provide an excellent fit to a three-factor model, it makes theoretical sense that the two factors (verbal WM and visual-spatial WM) share variance with a second-order factor. That is, both the verbal and visual-spatial WM measures were assumed to be monitored by a common source (executive system) because the tasks involve both simultaneous processing and storage. Thus, I computed a second-order factor to reflect cross-domain processing among the visual-spatial and verbal WM measures. The parameter estimates for the second-order model are shown in Figure 1 (bottom panel), and the indices for the model fit are reported in Table 3. Not surprisingly, the chi-square statistics for the

second-order factor model are no different than those presented for the three-factor model. This is because the two models were statistically indistinguishable but represent different hypotheses about the data. Although the chi-square statistic was significant, the model's  $\chi^2/df$  (2.52) was less than 3, which indicated an adequate fit to the data (Kline, 1998).

*Multiple group comparison.* An important question in this study was whether the covariance matrix fit both the younger and older children. A multisample analysis using structural equation modeling (Bentler, 2006) was computed on the covariance matrix for younger and older children. This analysis was done to answer the question as to whether WM and STM were distinct processes in young children. I tested whether a three-factor correlated model in which the STM measures (Forward digit, word span, pseudoword) loaded on one factor, visual-spatial WM measures (mapping/direction, visual matrix) on a second factor, and verbal WM (sentence span, conceptual span) loaded on a third factor held for both age groups. The theoretical model included cross-group constraints (Bentler, 2006). That is, the factor loadings and factor covariance were constrained to be equal across the two samples. Meredith (1993) considered this level of measurement configural invariance where the number of factors and pattern of factor loadings are considered to be identical across groups. The statistical fit for the two groups on the theoretical model is shown in the middle of Table 3. The model provides an excellent fit indicating that both age groups were comparable in terms of factor structure and loadings. However, follow-up stepwise Lagrange multiplier tests indicated that the constraint that accounted for most of the decrease in fit was the loading of visual matrix task on the visual-spatial factor for younger children. Thus, a revised model was tested where the visual matrix was not constrained to be equal across the two age groups. A comparison between the revised model and the theoretical model was significant (47.89–41.54),  $\Delta\chi^2(1) = 6.35, p < .05$ .

This finding indicated that the revised model was also a good fit to the data. Taken together, however, these results show that the two age groups did not differ in the structure of memory.

### *Path Analysis With WM as a Criterion (Endogenous) Variable*

**Path analysis.** The next analysis determined those variables that best accounted for age-related changes in WM. This analysis was done to answer the question as to whether age-related changes in children's WM are mediated by both STM and controlled attention. To this end, data were again analyzed using the EQS 6.1 (Bentler, 2006) and covariance structure models. Standard deviations and intercorrelations for all the variables are shown in Table 2. I report the null model and the theoretical model.

A diagram of the theoretical model tested is shown in Figure 2. To simplify the figure, the residuals are not shown. As shown, the theoretical model shows that age-related increases in performance on inhibition measures (fluency and random generation) influenced the second-order factor (executive processing). In addition, phonological knowledge and naming speed had direct paths to STM. I also included a path from age to STM because recent findings indicated that the development of storage ability (e.g., Bayliss et al., 2003, 2005) contributed unique variance to children's WM. To look at the separate contribution of the inhibition measures to WM, a path was established from fluency to random generation. I assumed that the two measures reflect different activities related to controlled attention: One was related to accessing knowledge and controlling for repetitions (fluency), whereas the other suppressed well-learned sequences (random generation). Likewise, a direct path was included from naming speed to phonological knowledge to partial the effects of each process on STM storage.

As shown in Table 3, the theoretical model was a good fit to the data. All paths were significant, and the results were consistent with my hypothesis suggesting that growth in controlled attention (fluency and random generation) is related to WM, and growth in speed and phonological knowledge is related to age-related changes in the phonological loop (STM). The theoretical model in Figure 2 shows a significant direct effect for fluency (standardized coefficient = .46), random generation (standardized coefficient = .27), and STM (standardized coefficient = .26) in predicting WM span. As shown, the disturbance term of the latent variable was .57. From the disturbance term (variance unaccounted for in the latent measure;  $D$ ) I can calculate  $R^2$  ( $R_j^2 = 1 - D_j^2$ ) or the proportion of variance accounted for in the direct path,  $j$ . The direct paths to WM accounted for 67% of the variance and therefore only 33% of the variance was unaccounted for. For the STM latent measure, significant direct paths were found for age (standardized path coefficient = .33), naming speed (standardized path coefficient = -.29), and phonological knowledge (standardized path coefficient = .06), which combined accounted for 41% of the variance. An interpretation of these standardized path coefficients can follow Cohen's (1988) recommendations where an absolute value of .10 represents a small effect, .30 represents a medium effect, and  $> .50$  represents a large effect. Thus, a small effect was found for phonological knowledge in predicting STM. A Wald test was computed to determine whether some of the paths could be deleted without changing model fit. The path from phonological knowledge to STM could be dropped. However, this path was

maintained because the path was significant in the theoretical model. I also investigated indirect effects on STM and WM.

The only significant mediating variable for WM was increases in the manifest variable of age (unstandardized path = .29,  $SE = .12$ , standardized = .76,  $t = 2.41$ ,  $p < .05$ ). No significant indirect paths were found for STM (all  $ps > .05$ ).

In summary, there were three important findings related to this analysis. First, the results show that activities related to controlled attention (fluency and random generation) contributed to age-related changes in WM span. Although previous studies have shown that WM span is related to speed and STM storage (Bayliss et al., 2005; Fry & Hale, 2000), the current study also shows that activities related to controlled attention contributed (in this case inhibition) important variance to WM span. Second, based on the magnitude of the standardized path coefficients, the largest effect size in terms of direct paths to WM was fluency. Finally, I found that the direction of the standardized path coefficients from speed to phonological knowledge and fluency to random generation was significant. These findings suggest that rapid naming has a direct effect on phonological knowledge and fluency has a direct effect on random generation.

### *Path Analysis With Fluid and Crystallized Intelligence as Criterion (Endogeneous) Measures*

For my next set of analyses, I determined whether the age-related paths in STM, fluency, and random generation to WM were maintained when WM predicted performance on measures of fluid and crystallized intelligence. I address the question as to whether WM predicts age-related increases in both fluid and crystallized intelligence. I also determine whether WM performance reflects age-related increases in controlled attention and storage when predicting performance on fluid and crystallized measures of intelligence. The theoretical model is shown in Figure 3. Except for the direct paths from WM to measures of intelligence, the model was similar to my theoretical model in Figure 2.<sup>6</sup>

As shown at the bottom of Table 3, the theoretical model was not a good fit to the data. The NNFI was below .90. A Lagrange test of this model indicated that a better fit would occur if paths were established between naming speed and fluency and naming speed and random generation. These modifications were added one at a time. When these paths were included in the modeling, there was a good fit of the model to the data. Overall, the revised model made theoretical sense because both the fluency and random generation measures involved time constraints. A comparison between the revised model and the theoretical model was significant (228.28–201.64),  $\Delta\chi^2(2) = 26.59$ ,  $p < .001$ . The standardized parameters for this model are shown in Figure 4. To simplify this diagram, I only present the standardized solutions for the latent

<sup>6</sup> Prior to the analysis, I determined whether it was necessary to eliminate extreme outliers from the path analysis. I calculated the estimated Mardia's Kurtosis [ $p(p + 2)$ , where  $p$  is the number of variables (19 in this case)] as 399. Mardia's estimate of Kurtosis was 14.72 for this sample and therefore I have multivariate data. The Mardia-based Kappa was .039. I also inspected the intercorrelations among the latent and manifest variables and these are shown in Table 4. As shown, the estimated correlation between the latent variables of phonological knowledge and reading are so high ( $r = .90$ ) that they are redundant. Two basic ways to handle this multicollinearity issue is to either eliminate these variables or combine them. Because I were interested in predicting reading, phonological knowledge was deleted from the subsequent analysis.

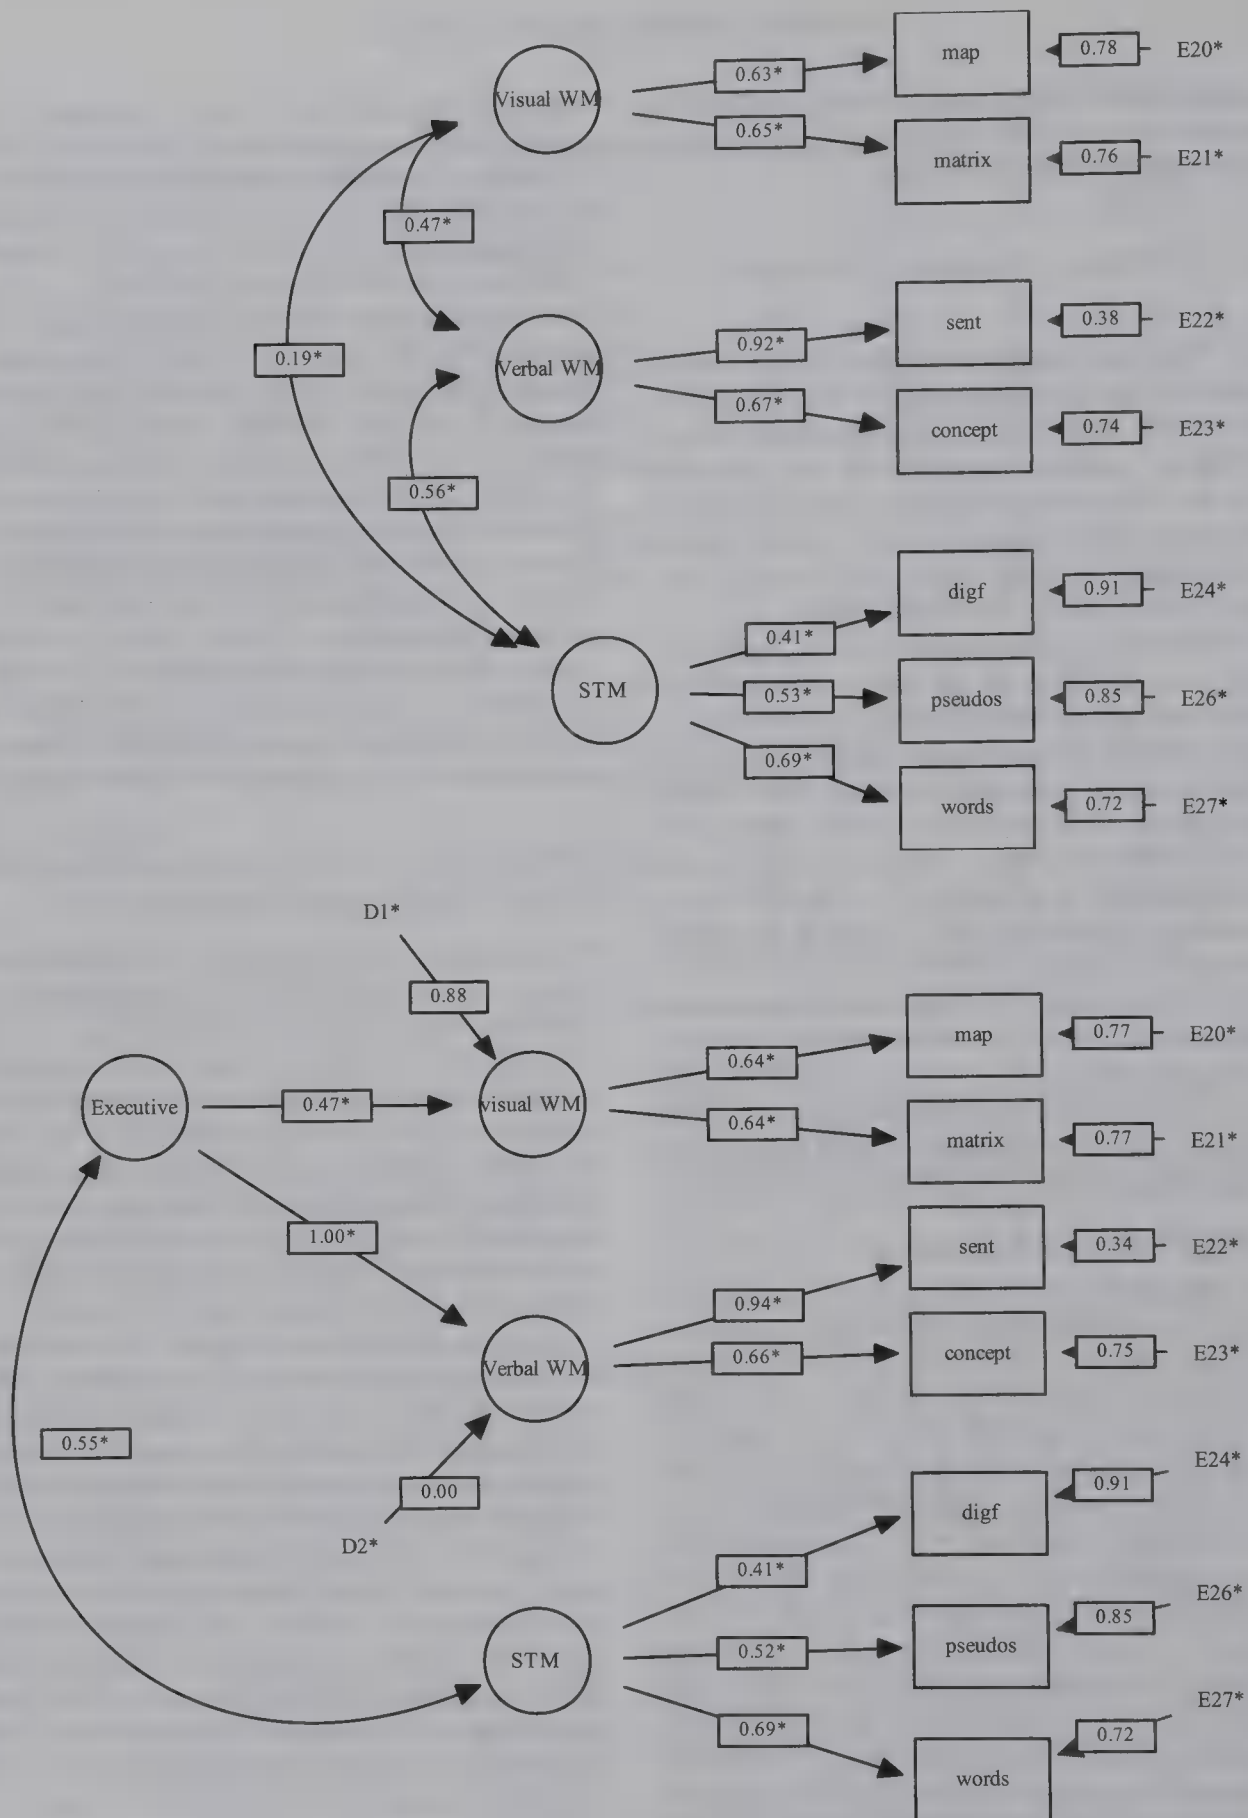

Figure 1. Confirmatory model for a correlated three-factor structure (top) and a second-order factor (bottom). Circles represent latent variables, and squares represent observed or manifest variables. Numbers on paths (path coefficients for the standardized solution) leading from latent variables to observed variables indicate the degree to which an observed variable was influenced by a particular latent variable. All path coefficients with an asterisk were significant at the .05 level. Paths leading to the observed variable that are not attached to latent variables are the residuals (or the degree to which the observed variable was influenced by unique factors). The top panel shows that the standardized factor loadings for the second-order model ranged in size from .41 to .94. The correlation between the latent measure of the second-order factor (referred to as the executive system) and STM storage (also referred to as the phonological loop) was .55. WM = working memory; STM = short-term memory; map = Mapping and Directions; matrix = Visual Matrix; sent = Listening/Sentence Span; concept = Conceptual Span; digif = Forward Digit; pseudos = Pseudoword Span; words = Word Span; D = disturbance; E = measurement error; \* = significance.

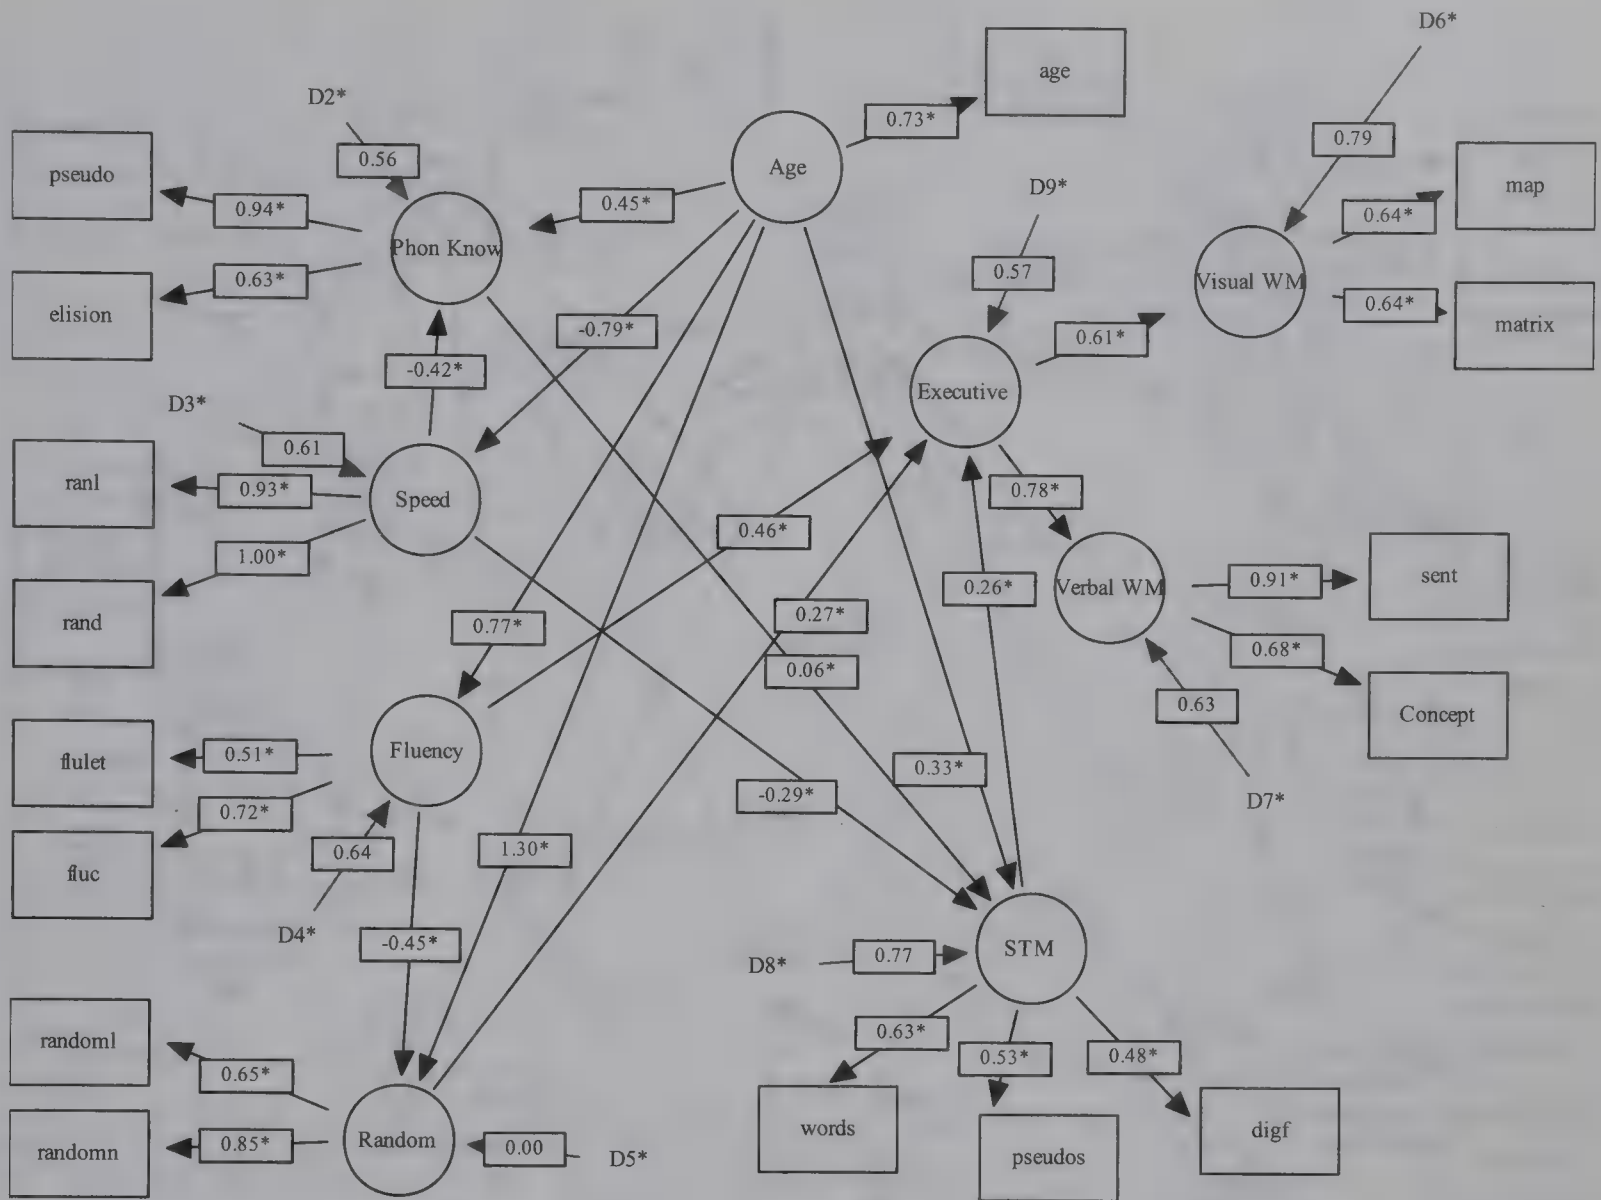

Figure 2. Path analysis to determine age-related correlates of working memory (WM) development. digitf = Forward Digit; pseudos = Pseudoword Span; words = Word Span; map = Mapping and Directions; matrix = Visual Matrix; sent = Listening/Sentence Span; Concept = Conceptual Span; Age = age in months (latent variable); age = age in months (manifest variable); pseudo = pseudoword reading task; elision = Elision or phonological deletion; ranl = rapid naming of letters; rand = rapid naming of digits; flulet = letter fluency; fluc = category fluency; randoml = random generation of letters; randomn = random generation of numbers; Phon Know = Phonological knowledge; Speed = Naming Speed; Random = random generation; STM = short-term memory; Executive = shared variance of verbal and visual WM tasks; D = disturbance; E = measurement error; \* = significance.

variables. Error terms and variables that made up the latent measures are not shown. The  $R^2$  for each direct path for each latent variable and the variables included in the direct paths (shown in the parenthesis) was as follows: fluid intelligence (executive processing + age) was 1.0, math (executive processing + age) was .98, reading (STM, executive process, age) was .94, naming speed (age) was .39, fluency (age) was .41, random generation (age) was .75, executive processing (fluency, STM, random generation) was .62, and STM (naming speed) was .57.

In terms of the magnitude of the standardized path coefficients, Figure 4 shows that the effect size was large for a path from executive processing to fluid intelligence (standardized path coefficient = .77) but moderate in magnitude when predicting math and reading (.30 and .42, respectively). As in the age-related model for WM, the paths from STM, random generation, and fluency to executive processing were significant, but the magnitude of the

coefficients were moderate to small (.10 for STM, .36 for random generation, and .49 for fluency).

Table 4 shows the indirect effects of the modeling. Indirect effects involve intervening variables (mediator variables) assumed to transmit some of the causal effect onto the endogenous variables (Kline, 2005, p. 65). Reported are the nonstandardized and standardized solutions for the decomposition of the paths. There are three important results. First, naming speed played a significant mediating role in fluid and crystallized intelligence. Second, increases in age, fluency, and random generation played mediating roles on measures of fluid intelligence and math. Finally, no significant indirect effects were found for STM.

I next used a hierarchical analysis to determine the mediating role of variables when sequentially entered into the analysis. The correlation matrix for this analysis is shown in Table 5. This was done because I wanted to systematically examine the age-related

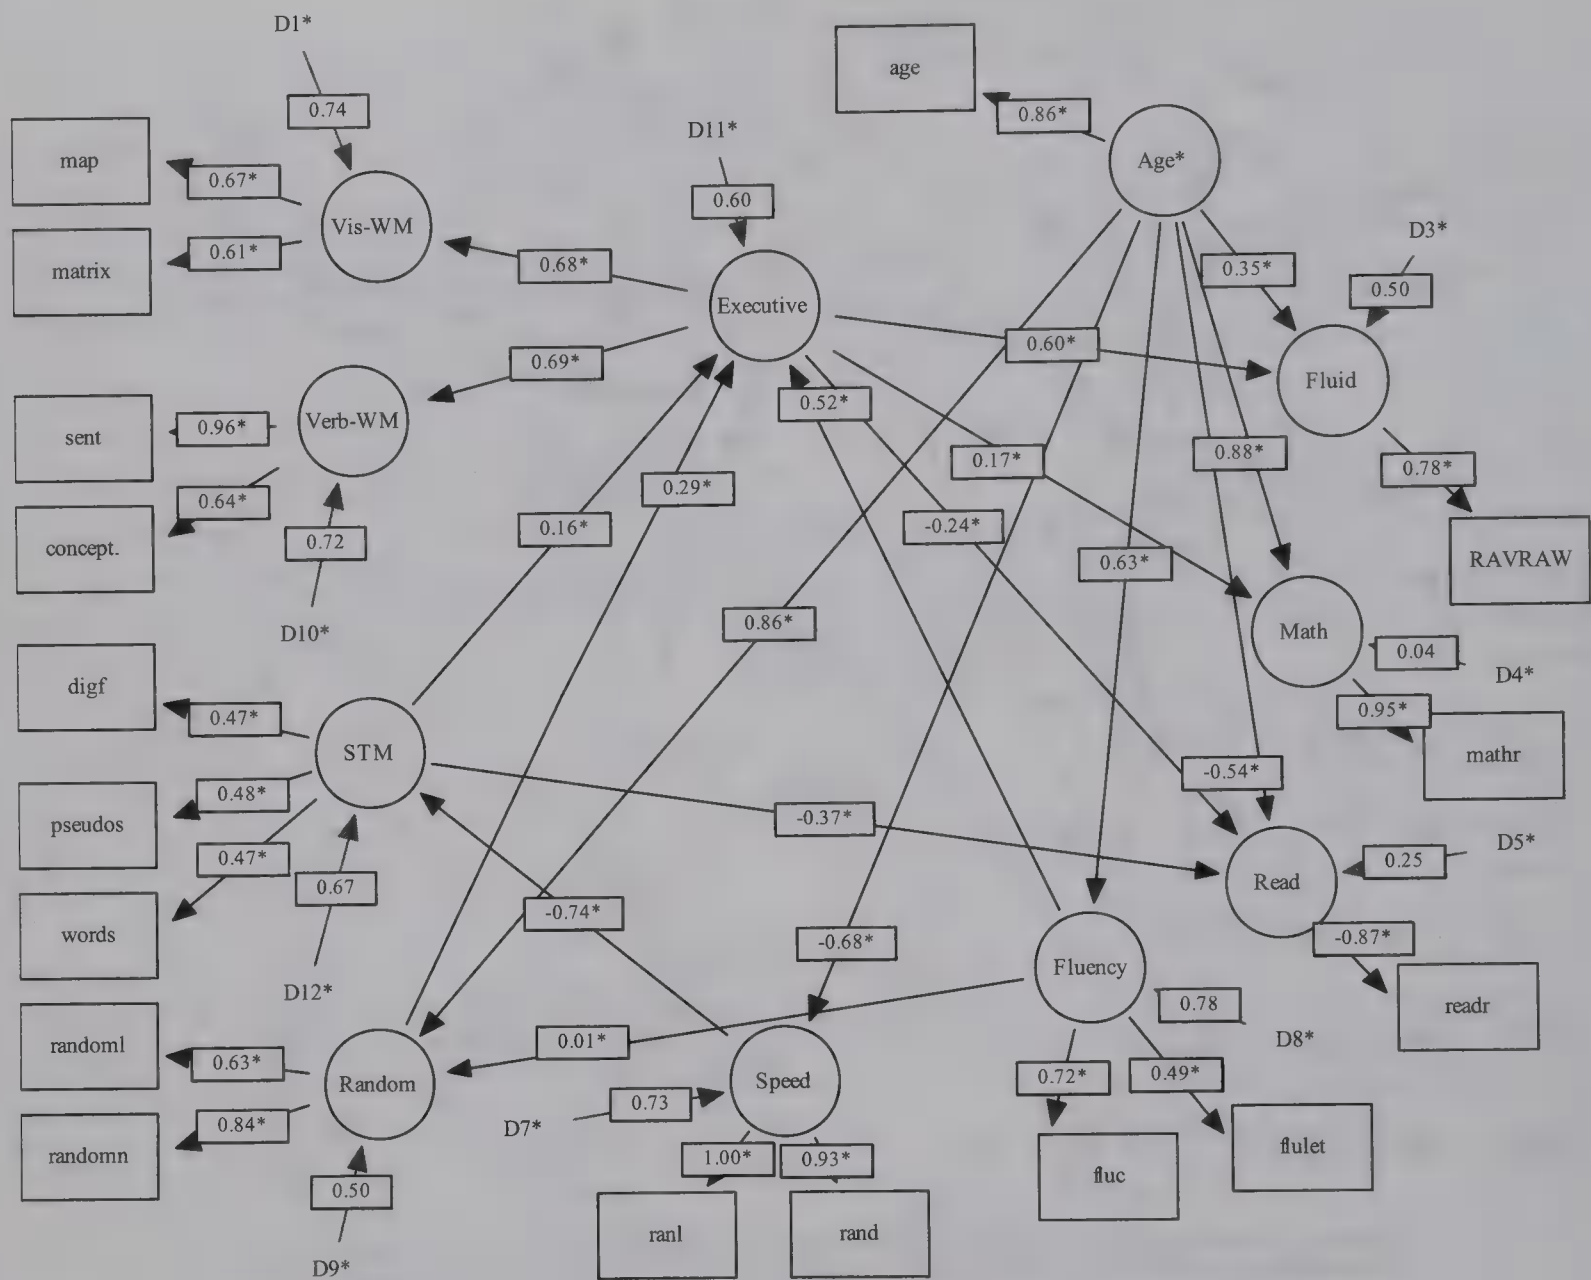

Figure 3. Path analysis representing the theoretical model to determine age-related contributor to fluid and crystallized intelligence. Speed = Naming Speed; Random = random generation; WM = working memory; STM = short-term memory; Executive = shared variance of verbal and visual WM tasks; Fluid = Raven Colored Progressive Matrices; Math = Wide Range Achievement Test—Third Edition Math subtest; Read = Wide Range Achievement Test—Third Edition Reading subtest; map = Mapping and Directions; matrix = Visual Matrix; sent = Listening/Sentence Span; Concept = Conceptual Span; digtf = Forward Digit; pseudos = Pseudoword Span; words = Word Span; randoml = random generation of letters; randomn = random generation of numbers; ranl = rapid naming of letters; rand = rapid naming of digits; flulet = letter fluency; fluc = category fluency; Verb = verbal; Vis = visual; readr = reading raw score; mathr = math raw score; RAVRAW = Raven raw score; D = disturbance; E = measurement error; \* = significance.

variance in fluid and crystallized intelligence, before and after controlling the variance ( $R^2$ ) associated with the introduction of a potential mediating variable (e.g., WM). The difference between the estimates of age-related performance given by the change in  $R^2$  shows the contribution of the mediating variable (e.g., WM) to the age-related differences in fluid and crystallized intelligence (see Salthouse, 2000, for a further rationale). Because this difference (increment in  $R^2$  or  $\Delta R^2$ ) was directly related to the degree to which age-related variance in intelligence was reduced when the mediator was controlled (e.g., WM), I then have a measure of the importance of that mediator. If significant residual age-related

differences remained after the entry of the postulated variable, then the age-related effect “represents influences that are unique to the target variable because the shared influences are presumably partialled out by the control of the other variable” (Salthouse, 2000, p. 4). Criterion measures and predictor variables were latent measures and manifest variables (e.g., age, fluid and crystallized intelligence) from the path analysis.

For my first set of analyses, I determined the amount of variance in fluid intelligence, math, and reading performance that was accounted for by (a) age alone (Model 1) and (b) age after WM and STM was partialled out (Model 2). I next tested (Model 3) whether

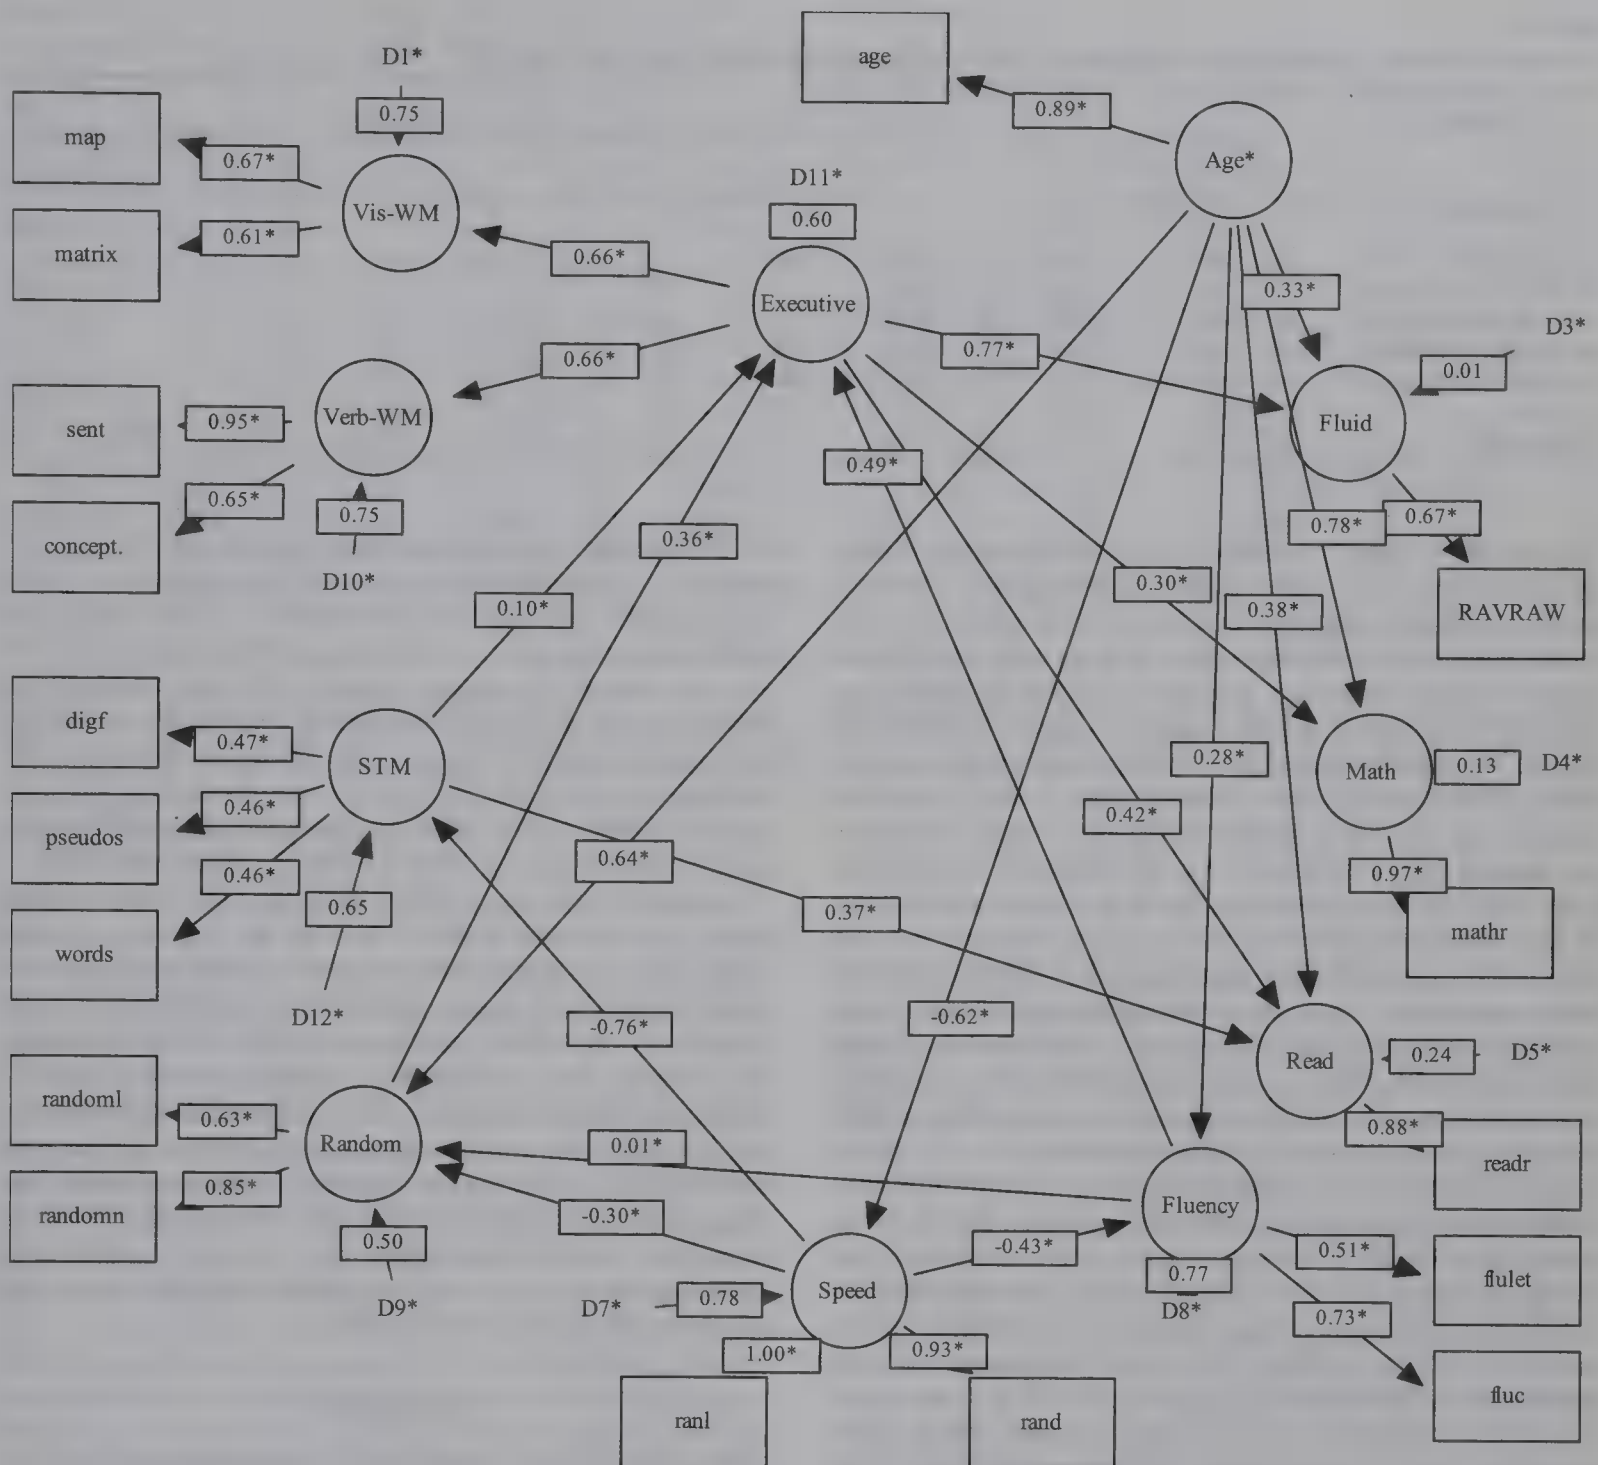

Figure 4. Revised model to determine age-related contributor to fluid and crystallized intelligence. Speed = Naming Speed; Random = random generation; WM = working memory; STM = short-term memory; Executive = shared variance of verbal and visual WM tasks; Fluid = Raven Colored Progressive Matrices; Math = Wide Range Achievement Test—Third Edition Math subtest; Read = Wide Range Achievement Test—Third Edition Reading subtest; map = Mapping and Directions; matrix = Visual Matrix; sent = Listening/Sentence Span; Concept = Conceptual Span; digf = Forward Digit; pseudos = Pseudoword Span; words = Word Span; randoml = random generation of letters; randomn = random generation of numbers; ranl = rapid naming of letters; rand = rapid naming of digits; fulet = letter fluency; fluc = category fluency; Verb = verbal; Vis = visual; readr = reading raw score; mathr = math raw score; RAVRAW = Raven raw score; D = disturbance; E = measurement error; \* = significance.

the significant variance related to WM (with the influence of STM partialled out) on measures of intelligence was eliminated when measures of the phonological system (naming speed) or activities related to executive processing (fluency, inhibition) were entered into the model. The results of my regression analysis for Models 1–3 are presented in Table 6. For each

criterion measure, the cumulative  $R^2$  associated with the addition of variables entered into the regression equation is presented at the bottom of the table. The unique variance in  $R^2$  associated with each variable when entered last in the equation appears in the 5th, 10th, and 15th columns, for fluid intelligence, math, and reading, respectively.

Table 4  
Correlations Among Latent and Manifest (Age, Fluid Intelligence, Math, Reading) Variables ( $N = 205$ )

Variable	1	2	3	4	5	6	7	8	9	10
1. Age	—									
2. Phonological	.60	—								
3. Speed	-.56	-.81	—							
4. Fluency	.55	.79	-.77	—						
5. Random Generation	.79	.80	-.83	.73	—					
6. Short-term memory	.48	.69	-.74	.77	.70	—				
7. Working memory	.49	.61	-.50	.75	.61	.72	—			
8. Fluid Intelligence	.52	.65	-.47	.60	.49	.47	.54	—		
9. Math	.65	.62	-.51	.59	.72	.46	.50	.47	—	
10. Reading	.67	.90	-.81	.78	.83	.68	.59	.64	.68	—

Inspection of Model 1 in Table 6 indicated that age contributed significant variance to all measures of intelligence. The total amount of variance related to the age variable in predicting intelligence was 27% for fluid intelligence, 42% for math, and 45% for word recognition (Model 1). The second analysis (Model 2) that entered WM and STM into the regression model accounted for 38%, 47%, and 62% of the variance in fluid intelligence, math, and reading, respectively. When Models 1 and 2 were considered together, the variance accounted for by age in fluid intelligence was reduced from 27% (Model 1) to 8% (Model 2). More specifically, there was approximately a 70% drop in the influence of age on fluid intelligence following the statistical control of WM and STM [ $.703 = (.27-.08)/.27$ ]. Likewise, entry of the WM and STM latent measure into the regression model reduced the age-related variance in math by 52% [ $.523 = (.42-.20)/.42$ ] and reading by 71% [ $.404 = (.45-.13)/.45$ ]. As shown in Table 6, WM contributed significant variance to fluid intelligence and math, whereas STM contributed unique variance to word recognition.

As shown in Table 6, Model 3 simultaneously entered fluency, inhibition, and naming speed into the regression model. When compared to Model 2, adding these processing variables to the model improved predictions by 6%, 12%, and 16% for fluid intelligence, math, and reading, respectively. The incremental improvement of  $R^2$  from Model 2 to Model 3 was significant when predicting fluid intelligence,  $F_{\text{inc}}(3, 198) = 10.00, p < .001$ ; math,  $F_{\text{inc}}(3, 198) = 20.80, p < .01$ ; and reading,  $F_{\text{inc}}(3, 198) = 53.00, p < .0001$ . Model 3 shows that the significant contribution of WM and age on fluid intelligence remained after entering STM and activities related to controlled attention, whereas the contribution

of STM and WM was eliminated when predicting performance on measures of crystallized intelligence. Significant predictors across all dependent measures were performance on the fluency and random generation measures. Inspection of Table 6 also shows that the total amount of variance related to the age in predicting intelligence was 6% for fluid intelligence, 1% for math, and 2% for word recognition. Thus, equations for Model 3 reduced the contribution of age by 78% ( $.27-.05/.27$ ) when predicting fluid intelligence, by 99% ( $.42-.01/.42$ ) when predicting math performance, and by 96% ( $.45-.02/.45$ ) when predicting reading performance.

In summary, the results yielded three important findings. First, Model 2 that included WM/STM reduced the variance accounted for by age in predicting fluid intelligence, math, and reading. I assumed that reductions greater than 50% were of important note. Reductions in age-related variance were 70% for fluid intelligence, 52% for math, and 71% for reading. Second, as shown in Model 2, the residual variance related to WM predicted fluid intelligence and math, but not word recognition. In contrast, the residual variance related to STM predicted word recognition. Finally, entering of the processing variables into the equation (Model 3) eliminated the significant contribution of memory variables in predicting measures of crystallized intelligence. This was not the case for predicting fluid intelligence.

## Discussion

This study assessed whether STM and WM operated as distinct processes in younger and older children and whether the processes of one system (e.g., phonological) superseded another (executive)

Table 5  
Indirect Effects When Predicting Measures of Intelligence

Causal variable: Indirect effects	Endogeneous variables

## Model significance

Model 1	$R^2 = .27, F(1, 203) = 78.04, p < .001$	$R^2 = .42, F(1, 203) = 148.67, p < .001$	$R^2 = .45, F(1, 203) = 169.67, p < .001$
Model 2	$R^2 = .38, F(3, 201) = 41.93, p < .001$	$R^2 = .47, F(3, 201) = 59.58, p < .001$	$R^2 = .62, F(3, 201) = 113.03, p < .001$
Model 3	$R^2 = .44, F(6, 198) = 32.81, p < .0001$	$R^2 = .59, F(6, 198) = 48.37, p < .001$	$R^2 = .78, F(6, 198) = 117.58, p < .001$

Note. STM = short-term memory; WM = working memory.

\*  $p < .05$ . \*\*  $p < .01$ . \*\*\*  $p < .001$ .

in mediating the influence of age-related changes in WM on measures of intelligence. I briefly review the models and the questions that directed the study.

Two models were tested. One model tested whether processes related to the phonological system (phonological loop) played a major role in predicting age-related performance on WM measures and whether the phonological system mediated the influence of WM on measures of intelligence. The model follows logically from literature on STM that links phonological skills to various aspects of children's crystallized intelligence (e.g., new word learning; Baddeley et al., 1998), comprehension (Perfetti, 1985), and arithmetic (e.g., Geary et al., 1999). This model suggests that because younger children are less efficient in the processing of phonological information, this may blur dissociations between measures of the phonological loop and the executive system. Thus, both WM and STM measures load on the same factor in younger children. The model assumes that phonological processing is more likely to mediate age-related differences in children's WM, fluid, and crystallized intelligence than measures of executive processing. I broadly defined phonological processing in this study as performance on latent measures of STM, phonological knowledge, and rapid naming speed. I broadly defined executive processing as performance on latent measures of WM, fluency, and random generation.

The second model posits that the influence of WM performance on measures of fluid and crystallized intelligence is due to executive processing, independent of the influence of the phonological system. The model predicts that regardless of age, WM and STM tasks load on separate factors because they draw on distinct systems: controlled attention and storage. Thus, I expected that STM and WM would operate as independent systems in terms of their influence on measures of fluid and crystallized intelligence. I assumed that controlled attentional processing was tapped when

measures of STM were partialled from the WM scores (e.g., Engle et al., 1999). I expected that WM would better predict measures of intelligence than STM. This assumption follows logically from the literature on fluid intelligence, reading, and math suggesting that abstract thinking requires the coordination of several basic processes (e.g., Engle et al., 1999; Just, Carpenter, & Keller, 1996; Kyllonen & Christal, 1990). I assumed that controlled attentional processing was related to individual differences in inhibition (fluency and random generation). Thus, I tapped two aspects of controlled attentional processing: one focused on the search for words while inhibiting repetitions and the other focused on inhibiting well-learned sequences.

In general, the results give support to the second model. I found that controlled attention moderated age-related changes in WM as well as the influence of WM on measures of intelligence. I found support for the influence of controlled attention (inhibition), as well as STM, in predicting age-related changes in WM. For the present sample, measures of inhibition and storage (STM latent score) contribute unique variance to WM. Thus, I find that the WM variable was related to measures of inhibition independent of STM storage. I now address three questions that directed this study.

### 1. Are WM and STM Distinct Processes in Young Children?

Our results show that STM and WM performance in elementary school children is distinguishable. The structure between the two types of tasks differs. The results show that WM and STM tasks load on separate factors in both younger and older children. The results further show that although STM (phonological loop) and WM (executive system) are correlated ( $r = .55$ ); they can and do operate independently of one another in predicting performance on measures of fluid and crystallized intelligence. More important,

data within and across the two age groups show comparable factor structures. A multisample analysis of the covariance structure showed a good fit suggesting that WM and STM measures are tapping comparable constructs across age groups.

The results of this study also show that the factor structure among children in the elementary grades was stable as well as comparable to the factor structure for STM and WM tasks found in adults (e.g., Engle et al., 1999). In terms of stability, I did not find a qualitative change in the structure of the memory tasks between the two age groups. A three-factor model captured performance in both the younger and older groups of children. I tested whether a one-factor model might have been more adequate for the older than the younger age, but I did not find support for either of these models. When generalizing to adult samples, as found in the Engle et al. (1999) study, I also found that letter, digit, and word span tasks define the STM factor, whereas tasks that include the combination of both processing and storage define the executive component of the WM factor. I defined the processing component of my WM measures as that part of the memory task that directed children to respond to discrimination questions about recently encoded information, whereas I defined the storage component as that part of the task that required children to retrieve recently encoded information. In sum, my findings do not support studies showing WM and STM as loading on a similar factor in children (e.g., Hutton & Towse, 2001).

The above findings are important because Engle et al. (1999) suggested that rehearsal and chunking may play a role in the poor differentiation of STM and WM tasks in children. They suggested that because these processes are less automated in children, then perhaps an executive system might be invoked on STM tasks that in turn would make STM and WM less distinct. I did not find direct support for this hypothesis. In fact, the correlations between STM and WM were substantially weaker than that of the Engle et al. study ( $r = .70$  vs.  $.55$ ) suggesting greater independence among these measures in children than adults.

## 2. Do Age-Related Improvements in Controlled Attention and/or Storage Underlie Age-Related Changes in Children's WM?

The path analysis found that approximately 70% of the variance in WM was attributable to STM storage, fluency, and random generation. Thus, the results clearly support the notion that the development of WM is related to both increases in storage and controlled attention in young children. The path analysis, however, gave us some unique insights in how these age-related changes influence WM performance. Naming speed had a significant path to STM, suggesting that naming speed was important to storage. Thus, although age-related changes in controlled attention activities (random generation, fluency) and STM have a direct path to WM, STM storage is influenced by age-related increases in phonological knowledge and naming speed. Although phonological knowledge had a significant path to STM, the effect size for this path was substantially smaller than naming speed.

Overall, these results on WM are consistent with recent studies that have shown that age-related changes in WM are related to storage variables (Bayliss et al., 2005). However, WM is made up of more than just storage. More specifically, Bayliss et al. (2005) found that "age-related improvements in storage ability were important for complex span independent of

any changes in processing speed and conversely, that age-related changes in speed of processing contributed to complex span performance independent of changes in storage ability" (p. 592). I found clear support that age-related changes in STM predicted age-related changes in WM. Although my measure of speed (naming speed) differed from that of Bayliss et al. (2005; reaction time of verbal and visual-spatial search tasks), and therefore a direct comparison between the two studies cannot be made, my results suggest that speed had a direct effect on STM storage and not on WM. Further, I were able to specify that storage is made up of two components: phonological knowledge and naming speed. More important, in contrast to the other studies in which speed predicts WM, I did not find that naming speed played a mediating role on WM performance. However, as shown in Table 4, latent measures of naming speed and STM/WM were moderate ( $-.74$  and  $-.50$ , respectively), and in the same range as raw scores in the Bayliss et al. (2005) study (see Table 2; correlations between storage tasks and basic speed measures were  $-.46$  and  $-.47$ ). However, my analysis had the advantage of including measures of controlled attention. In general, my results are in line with studies using adult samples that have found verbal storage in STM accounts for age-related effects on WM measures. For example, McCabe and Hartman's (2003) results showed that storage capacity (STM) in language processing was an important predictor of complex WM performance. However, as an extension of these studies I found that processes related to controlled attention (inhibition), along with STM, played the major role in predicting age-related changes in WM. STM, fluency, and random generation each contributed unique variance to WM. The path analysis showed that approximately 70% of the WM variance could be attributed to STM and controlled attention measures.

In summary, the results show that WM in children is made up of controlled attention and STM, whereas STM is made up of naming speed and phonological knowledge.

## 3. What Processes Influence WM on Age-Related Changes in Intelligence?

Answering this question was important because the processes that mediate age-related development in WM span may not be the same processes that mediate the influence of WM on intelligence. In my model testing, I determined whether the theoretical model that fit the processes that mediate WM span also play an important role when WM was used to predict fluid and crystallized intelligence. That is, the theoretical model assumed that age-related changes in controlled attention activities and storage had a direct influence on WM span that in turn had a direct effect on intelligence. Unfortunately, the aforementioned model was not a good fit to the data when predicting fluid and crystallized intelligence and was revised. The revised model found that direct effects from naming speed to inhibition measures were necessary. Thus, naming speed played a significant mediating role between WM and measures of intelligence.

When the analysis focused on fluid and crystallized intelligence in isolation, the hierarchical regression analysis showed that the residual variance related to WM predicted fluid intelligence and math, whereas the residual variance related to STM predicted reading. More important, there was approximately a 70% drop in the influence of age on fluid intelligence, a 52% drop in math, and

a 71% drop in reading when measures of STM and WM were entered into the analysis (see Model 2). The results in Table 6 also showed that for the full model, entry of controlled attention measures into the regression model eliminated the significant contribution of WM to measures of crystallized intelligence, but not fluid intelligence. Thus, the question emerges as to whether the residual variance attributed to WM and fluid intelligence reflects controlled attention (e.g., Engle et al., 1999). I assumed that controlled attention was related to the latent measures of fluency and random generation. There is good reason to assume this because the correlation between the latent measures of WM and fluency was .75 and between WM and random generation was .61 (see Table 4). Further, there is good reason to assume from the literature that the measures tap some aspects of controlled attention, such as the inhibition of well-learned sequences (e.g., Towse, 1998). However, I found that entry of these measures in the regression models eliminated the significant contribution of WM only on measures of math and reading, but not on fluid intelligence. What these findings suggest to us is that the residual variance related to WM (controlled attention) in predicting fluid intelligence is mediated by processes other than inhibition. Further, because my measures were not pure measures of inhibition, I may not have adequately tested the inhibition model. Taken together, however, my results extend Engle et al.'s (1999) findings to children that when controlling for the correlations between WM and STM, the residual variance for the WM factor predicts fluid intelligence.

### Implications

There are two implications related to my findings. First, age-related changes in WM are made up of more than storage and speed. Measures of controlled attention, in this case inhibition, must also be included in the modeling. Some developmental models have indicated that younger children are less resistant to interference than older children (see Bull & Scerif, 2001; Brainerd & Reyna, 1993; Chiappe, Hasher, & Siegel, 2000; De Beni, Palladino, Pazzaglia, & Cornoldi, 1998). There are also several memory studies with adult samples showing that inhibitory capabilities are a determinant of WM differences. For example, Hasher, Stoltz, Zacks, and Ryma (1991) have shown that age differences in WM and comprehension in language are driven by an inhibitory deficit. Older adults show difficulties on WM tasks not because of a smaller capacity but because an inhibitory mechanism fails to regulate the contents of WM. Failure comes when relevant and irrelevant information competes for retrieval and control. In Hasher, Lustig, and Zacks's (2007) view, then, inhibition drives WM capacity. When applying this model to age-related changes in children's WM, some researchers argue that poor inhibition underlies younger children's ability to prevent irrelevant information from entering WM during the processing of targeted information (see Passolunghi & Siegel, 2001, for a discussion of this model). Younger children have difficulty preventing unnecessary information from entering WM and, therefore, are more likely to consider alternative interpretations of material than older children. This interpretation fits with my findings, as well as several models with adults that explain individual differences in WM performance as related to inhibitory mechanisms (e.g., Cantor & Engle, 1993; Conway & Engle, 1994; also see Barrett, Tugade, & Engle, 2004, for a review).

In support of this model, I found that inhibition (fluency and random generation) measures predict WM performance as well as performance on measures of fluid and crystallized intelligence. Thus, WM tasks tap the child's ability to activate relevant information as well as suppress irrelevant information that in turn places demands on a general capacity system. Although I see the inhibition model as one of several processes underlying the residual variance related to WM, I do not see it as the sole process underlying age-related differences in WM. A special account has to be given to the role of other processes, especially because WM predicted fluid intelligence when all measures of inhibition were entered into the regression model.

The findings also give support to a popular model of WM related to speed of processing. A simple version of this model states that young children are slower at processing language information than older children and that such reduced processing on the younger participants' part underlies their poor WM performance. Several models of WM assume that operations related to language are time consuming (e.g., Ackerman, Beier, Boyle, 2002; Salthouse, 1996; Verhaeghen & Salthouse, 1997). Therefore, speed of processing may underlie the general pattern of age-related changes in WM noted in the present study. Further, Kail (1993) argued that a common pool of cognitive resources that relate to processing speed are used to perform a variety of tasks, with the pool increasing across ages in children. Clearly, my findings show a significant correlation between latent measures of naming speed and latent measures of STM and WM ( $r = -.74$  and  $-.50$ , respectively; see Table 4). However, I found that naming speed is primarily related to the storage component of WM. It is important to note, however, that my study focused on naming speed and therefore the results may have been different if measures of speed related to decision making, reaction time, and related measures would have been measured.

Second, the relationship between the basic cognitive capacities of STM, WM, and processing speed with measures of fluid and crystallized intelligence was substantial. Latent measures of basic capacities were each found to correlate substantially with the intelligence measures, and the basic cognitive factors in the SEM accounted for over 93% of the variance in fluid and crystallized intelligence. The results suggest a strong link between children's intelligence and basic cognitive processes. The study replicates previous studies on the importance of basic cognitive processes in predicting academic performance. For example, Luo, Thompson, and Detterman (2006) in their recent large-scale analyses found similar relations between the basic cognitive factors of STM, WM, and processing speed and a scholastic performance factor. The variability in scholastic performance explained by the basic capacities was found to be close to 90% or more on the level of latent factors.

### Conclusion

In conclusion, the present results can address the question "What does the development of WM in young children entail?" The development of WM involves two major components: controlled attention and storage. I found that age-related improvements in WM are significantly related to individual differences in controlled attention and STM, whereas phonological knowledge and naming speed mediate STM storage. The two systems, while related, can operate independent of one another. Our findings

indicate that components of STM and WM load on distinct factors in children as young as 6 years of age. I also found that when WM is used in predicting measures of intelligence, naming speed plays a significant mediating role. That is, while WM growth is related to controlled attention and storage, other processes, such as naming speed, come into play when mediating the role of WM on measures of intelligence.

# When Less Is More in Cognitive Diagnosis: A Rapid Online Method for Diagnosing Learner Task-Specific Expertise

Slava Kalyuga  
University of New South Wales

Rapid cognitive diagnosis allows measuring current levels of learner domain-specific knowledge in online learning environments. Such measures are required for individualizing instructional support in real time, as students progress through a learning session. This article describes 2 experiments designed to validate a rapid online diagnostic method that was inspired by experimental procedures applied in classical cognitive studies of chess expertise. With the described rapid verification method, learners are required to rapidly verify suggested steps at various stages of a problem solution procedure. In this study involving 33 university students, a high degree of correlation was found between rapid testing scores and results of in-depth cognitive diagnosis based on observations of problem-solving steps using video recordings and concurrent verbal reports in the domains of kinematics (vector addition motion problems) and mathematics (transforming graphs of linear and quadratic functions). The article discusses possible applications of the suggested method in adaptive learning environments.

**Keywords:** online cognitive diagnosis, rapid diagnostic method, expertise, learner-tailored instruction

*Task-specific expertise* is the ability of a person to perform fluently in a specific class of tasks. It has a more narrow definition than *professional expertise* (e.g., Ericsson & Charness, 1994), and it is an essential part of academic domain-specific expertise within the model of domain learning (Alexander, 2004). For example, a secondary school student could reach a top level of task-specific expertise in solving simple linear algebra equations, although he or she still would be far from becoming not only an expert mathematician but also an expert in school-level mathematics. Although both professional expertise and academic domain learning expertise include additional essential attributes (e.g., a systemic vision of the field, well-developed metacognitive skills, strategic processes, attitudes and interests), a common major feature of all types of expertise is the availability of a well-organized domain-specific knowledge base (Bransford, Brown, & Cocking, 1999). In the case of task-specific expertise, it is knowledge structures (including strategies and procedures) used in solving a specific class of tasks. Because of the full or partial automation of such structures, experts are able to rapidly perform advanced solution stages by integrating procedures and skipping some (or all) intermediate steps (Blessing & Anderson, 1996; Koedinger & Anderson, 1990; Sweller, Mawer, & Ward, 1983).

Task-specific expertise is a necessary prerequisite of both high-level professional expertise and academic domain learning expertise. Experts of both these types are also highly proficient in solving key classes of tasks within their areas of expertise. Therefore, in education and training, developing expertise in main classes of tasks is an important condition of mastering specific subject domains. Within a cognitive load framework (see Van

Merriënboer & Sweller, 2005, for a recent overview), the importance of developing task-specific expertise is explained by the need to free cognitive resources that are required for learning higher level tasks and developing flexible and transferable skills.

A number of recent studies have demonstrated significant interactions between levels of learner task-specific expertise and optimal instructional formats (expertise reversal effect; for overviews, see Kalyuga, 2005; 2006b; Kalyuga, Ayres, Chandler, & Sweller, 2003). Many instructional procedures and formats that are effective for novice learners may become ineffective, or even detrimental, for expert learners and vice versa. The major instructional implication of the effect is the need to adapt the design of learning environments and levels of instructional guidance to changing levels of learner expertise in a corresponding class of tasks. To be able to do this dynamically, in real time (e.g., during a single tutoring session), appropriate rapid methods of cognitive diagnosis are required that are capable of accurately detecting different levels of learner task-specific expertise. Such rapid methods are especially important for adaptive online learning environments and Web-based courses that cannot use traditional paper-based diagnostic instruments (or their online equivalents) in real time. E-learning courses and tutorials are becoming widespread; however, their adaptive capabilities are usually limited to tailoring instructional content to relatively superficial learner attributes (e.g., preferences, interests, choices, history of previous online behavior) and are not based on fundamental cognitive characteristics such as learner knowledge base.

Traditional methods that are best suitable for diagnosing individual levels of expertise in a domain are based on interviews and think-aloud protocols as learners perform domain-specific tasks. Such verbal reports may provide near-direct evidence about real cognitive processes, ways of reasoning, and underlying learner knowledge structures. However, these mostly laboratory tools are not suitable for the real-time online evaluation of learner progress during instruction. On the other hand, traditional educational tests either have limited diagnostic capabilities or are too time consum-

I thank Lauren Willis for her assistance in collecting experimental data.

ing. For example, common multiple-choice items at best indicate remote results of various possible solution strategies rather than information about actual solution steps. In such tests, knowledge-based expert solutions and trial-and-error novice efforts may receive the same scores. The rapid diagnostic approach attempts to build on the strengths of verbal reports and avoid the limitations of multiple-choice measures.

This article describes a rapid online diagnostic technique, the rapid verification method, and a series of experiments designed to validate the method in two different task domains. With this method, learners are required to rapidly verify suggested steps at various stages of the solution procedure. The method realizes a general rapid diagnostic approach based on our knowledge of human cognitive architecture, especially interactions between working memory (WM) and long-term memory (LTM) structures (Kalyuga, 2006b; Kalyuga & Sweller, 2004).

### A Rapid Testing Approach in Cognitive Diagnosis

WM is a setting for people's conscious cognitive processes. It is severely limited in duration and capacity when dealing with unfamiliar information (Baddeley, 1997; Miller, 1956; Peterson & Peterson, 1959). However, in well-known domains, the available knowledge base in LTM allows people to encapsulate many elements of information into larger chunks that are treated as single units in WM. Available LTM knowledge structures essentially define the characteristics of WM by effectively extending its capacity and reducing WM load. Therefore, WM capacity is not a stable characteristic of a learner but always depends on the learner knowledge base and directly reflects the available domain-specific knowledge structures. Accordingly, a diagnostic method based on immediate evaluation of units of WM content when an individual approaches a task could be used for measuring levels of expertise in the corresponding task domain. The method would actually evaluate the extent to which WM limits have been altered by domain-specific knowledge structures held in LTM.

Because of the association with stable LTM structures, the content of experts' knowledge units in WM is sufficiently durable and resistant to temporary interferences (Ericsson & Kintsch, 1995) to allow a working diagnostic procedure. If a person has a well-learned strategy for solving a specific class of tasks, he or she will immediately apply it when encountered with a task from this class. Someone without such knowledge will start searching for a solution randomly. It is practically possible to determine the content of knowledge (if any) used in a specific task situation, for example, by analyzing the concurrent (think-aloud) verbal reports. This method, however, is time consuming and difficult to use in online learning environments.

Some experimental procedures used in classical cognitive studies of chess expertise by De Groot (1965) and Chase and Simon (1973) suggested another idea. In those studies, professional grand masters performed considerably better than weekend players in reproducing briefly presented (for few seconds) chess positions taken from real games. There were no significant differences, however, for random configurations of chess figures. A schematic knowledge base of a huge number of different real game configurations held in grand masters' LTM allowed them to reproduce chess positions by familiar chunks rather than by individual chess figures without overloading WM.

Chess grand masters know the best move for each of the remembered typical real game configurations. Therefore, a rapid test of chess expertise could be based on presenting typical game configurations for brief periods of time and asking players to rapidly indicate their first move for each situation (essentially these are tasks that grand masters face when playing simultaneously on many chess boards). Applying this idea to the rapid diagnostic assessment of task-specific expertise in school mathematics resulted in the first-step diagnostic method (Kalyuga & Sweller, 2004). Learners were presented for a limited time with a series of tasks with gradually changing levels of complexity and were asked to rapidly indicate their first step toward solution of each task. The first step would involve different cognitive processes for individuals with different levels of task-specific expertise. For example, experts would bring their well-automated higher level procedures that allow them to rapidly generate advanced stages of the solution or even final answers to relatively more difficult tasks and skip many intermediate operations. On the other hand, complete novices may only be able to start the first attempt in their random search (e.g., trial-and-error) approach to even simple tasks. Therefore, different first steps would indicate not only the availability but also different levels of acquisition of corresponding knowledge structures in the learner's LTM.

Validation studies of the first-step method in algebra, coordinate geometry, and arithmetic word problem solving indicated significant correlations (.85, .92, and .72, respectively) between performance on these tasks and traditional measures of knowledge that required complete solutions of corresponding tasks (Kalyuga, 2006c; Kalyuga & Sweller, 2004). Test times were reduced by factors of up to 4.9 in comparison with traditional test times. The first-step method was sensitive to underlying knowledge structures and was sufficiently rapid. The method was used for optimizing levels of instructional guidance in adaptive computer-based tutoring in solving linear algebra equations (Kalyuga & Sweller, 2004, 2005). At the beginning of a session, each learner was allocated to an appropriate level of guidance according to the outcome of the initial rapid diagnostic test. Depending on the outcomes of the rapid diagnostic probes during instruction, the learner was allowed to proceed to the next stage of the session or was required to repeat the same stage and then take the rapid test again. At each subsequent stage of the tutoring session, a lower level of instructional guidance was provided to learners, and a higher level of the rapid diagnostic tasks was used at the end of the stage.

### Rapid Verification Method

Another possible approach to a rapid evaluation of chess expertise may be based on presenting a real game configuration for a brief period of time, followed by displays of several possible (both suitable and unsuitable) moves for this configuration, one display at a time. A player should rapidly verify the suitability of each of these moves. A similar approach to the rapid diagnostic assessment of task-specific expertise could also be applied in an online educational context. Learners could be presented with a series of possible (correct and incorrect) steps corresponding to various stages of the task solution procedure and asked to rapidly verify the suggested steps. Specific forms of responses could be clicking on displayed on-screen buttons or pressing specified keys on the computer keyboard (e.g., *correct*, *incorrect*, or *don't know*). An

important advantage of this rapid verification method over the first-step technique is its better suitability for computer-based and online applications, especially in task areas in which solution steps cannot be specified precisely in advance (e.g., when learners need to draw graphical task representations).

The ability to rapidly verify advanced stages of a solution procedure is based on the effectively expanded WM capacity and reduced cognitive load due to available task-relevant knowledge structures (e.g., procedures, rules). The levels of acquisition of this knowledge could be measured by an appropriately defined scoring method that reflects different levels of performance in verifying suggested solution steps. The required rapidness of learners' responses is not only a means of reducing testing time. More importantly, it is essential for capturing knowledge structures that learners actually use while approaching a task and before any lengthy chains of reasoning or searching could be applied, thus diagnosing the level of knowledge-based expertise.

The rapid diagnostic approach could be considered as a form of dynamic assessment that measures students' ability to move on with a task solution given a certain level of additional guidance (Bransford & Schwartz, 1999). In the case of rapid verification tasks, the additional guidance is provided by the depiction of a gradually changing number of previously completed steps. When presenting learners with various stages of a solution procedure for rapid verification, researchers use the varying levels of scaffolding to determine the level of learner proficiency in handling increasingly difficult situations.

The rapid verification method was actually used for optimizing levels of instructional guidance and individualizing instructional procedures in an adaptive computer-based tutorial in kinematics (Kalyuga, 2006a). As levels of learner expertise increased according to online rapid verification tests, the levels of provided guidance were reduced. On the other hand, for learners with insufficient levels of knowledge, more guidance was provided in the form of worked-out solution steps. However, in contrast to the first-step method, no validation studies were conducted for this method. Test scores are valid if they are obtained from a measure designed, or method implemented, to evaluate an attribute, construct, or variable that has been defined clearly on the basis of a theory and substantive reviews of literature. Using correlations of the test scores with other measures of the attribute as evidence that the test assesses the intended attribute is referred to as establishing the concurrent validity of the test. Thus, investigating whether the rapid assessment results would correlate highly with more traditional measures of task-specific expertise is needed to support the claim that the method actually measures the levels of learner expertise.

For example, there could be concerns that replacing the first-step rapid diagnostic method with a rapid verification technique would effectively turn a test of organized knowledge structures into a recognition test measuring knowledge of shallow task characteristics. The rapid verification method actually uses a recognition test format for verifying suggested solution steps. However, learners need to recognize intermediate advanced steps in a solution procedure, and these steps have to be rapidly constructed first by retrieving and using available knowledge in LTM. These processes involve more complex cognitive activities and higher levels of knowledge than those required by traditional recognition tests. Therefore, it is assumed that this method is diagnostically more

powerful than simple recognition tests and could be used for measuring levels of learner task-specific expertise. However, this assumption needs to be supported by studies of concurrent validity of the diagnostic procedure.

Thus, the experimental studies reported in this article were designed to answer the following research questions:

1. Is the suggested online verification procedure a valid diagnostic method capable of detecting different levels of acquisition of domain-specific knowledge structures? The hypothesis is that the rapid verification test results will correlate significantly with alternative traditional measures of task-specific expertise, thus demonstrating a high degree of concurrent validity.
2. Is the suggested online verification procedure a rapid method that could be completed fast enough for real-time applications? The hypothesis is that the rapid verification test will allow a substantial reduction of diagnostic assessment time in comparison with alternative traditional measures of task-specific expertise.
3. Will the suggested rapid verification procedure generalize to different task domains? The hypothesis is that the rapid tests will demonstrate high degrees of validity indicators in different task areas.

In addition to validating a new diagnostic method that implements the rapid diagnostic approach, the novelty of this study is also in using task domains (vector addition problems and graph transforming tasks) that essentially rely on graphical representations of task situations. Most previous studies of the rapid first-step diagnostic technique used numerical-only tasks. Another essential improvement is observing participants' actual problem-solving steps using video recordings and concurrent verbal reports as better criterion measures of task-specific expertise than students' records of problem-solving steps used in previous studies. Thus, in the traditional paper-based test, participants were required to provide complete solutions of tasks similar to those used in the rapid verification test. The participants' on-paper actions and think-aloud verbalizations were recorded and analyzed. In order to determine actual time reductions associated with rapid testing in comparison with the traditional test, I used self-paced tasks in both tests.

In both test conditions, more knowledgeable learners were expected to perform their tasks with lower levels of cognitive load than relative novices because of effectively increased WM capacity due to the available knowledge base. Therefore, I also included the evaluation of cognitive load in the procedure to provide another indicator of levels of learner expertise in addition to the task performance scores. Previous cognitive load research studies have indicated that a simple subjective rating scale of task difficulty could be an effective means of measuring cognitive load imposed by instructional materials (e.g., see Paas, Tuovinen, Tabbers, & van Gerven, 2003, for an overview).

If the tests actually measure levels of learner task-specific expertise, difficulty ratings are expected to show significant negative correlations with test scores: Because of reduced WM load, tasks in both tests should be relatively easier for more proficient learners than for less experienced participants. In this study, the measures of cognitive

load may also provide an indicator of participants' actual engagement in knowledge-based higher level cognitive activities during rapid assessment tasks. If the rapid tests were based only on simple recognition of surface task characteristics, the task difficulty would not differ for learners with different levels of expertise. Consequently, there would be no correlations between difficulty ratings and test scores for rapid verification tasks.

### Experiment 1

Experiment 1 was designed to investigate whether rapid verification scores in a task domain in kinematics could be validated by correlating highly with the results of observations of participants' paper-based problem solving steps and their concurrent verbal reports. The experimental tasks represented a class of problems in kinematics called *vector addition motion problems*. A typical task in this domain requires adding two vectors that are positioned at a certain angle to each other, for example, "A sea wave is traveling at 8 m/s towards the beach. A swimmer moves at 3 m/s in a direction perpendicular to the direction of the wave. What is the velocity of the swimmer relative to the ground?" During the rapid verification test, students were presented with a set of possible (correct and incorrect) intermediate solution steps and were asked to rapidly verify the correctness of these steps. More knowledgeable learners presumably should be better able to rapidly recognize more advanced intermediate solution moves than less knowledgeable learners.

For example, a person who knows that a vector approach should be applied but who has not practiced graphical addition of vectors may be able to verify correctly only a diagram with two perpendicular vectors as a valid step toward the solution. An individual who has more experience with vectors may rapidly verify perpendicular vectors with numerical values assigned to the length of each vector. Another person who is familiar with the vector addition procedure may also verify immediately a diagram representing the graphical addition of these vectors. Someone with more experience in adding vectors might be able to rapidly verify a numerical expression for the Pythagorean theorem that is used in solving this class of tasks. A learner with substantial experience in solving such tasks may even be able to verify a numeric expression representing the final answer without a diagram present.

### Method

#### Participants

Thirty-three university students (18 women and 15 men, age 18–25) participated in this experiment. They represented different years of study: 17 undergraduate, 3 graduate, and 13 postgraduate students. Participants also represented variety of subject areas: 12 students were involved in technical areas (including mathematics, mechanical engineering, computer engineering, biotechnology), and 21 were from nontechnical areas (education, psychology, medicine, law, management, international studies). In order to have a wide range of students' familiarity with the domain and different levels of their task-specific expertise, I deliberately recruited the participants from various areas of academic specializations with different degrees of involvement of mathematics. Brief pretest interviews indicated that participants represented different levels of expertise in the area of kinematics ranging from novices

(some still remembered that they had studied related material in their high school science courses) to experienced individuals studying university engineering and mathematics courses. The scores obtained from the rapid verification tasks and traditional measures of expertise in the experiment confirmed the initial pretest rough evaluations. Students with more expected experience in the domain performed better on the experimental tasks. For example, according to the values of rapid test scores (out of the maximum possible total score of 75), 2 participants representing nontechnical fields were in the range from 0 to 25 (the lower third), another 19 nontechnical participants were in the range from 26 to 50 (the medium third), and 11 participants representing technical areas were in the range from 51 to 75 (the upper third). The students had not been exposed to the specific materials used in the study prior to the experiment. They were paid AU\$20 for their participation in the experiment.

#### Materials and Procedure

Each participant was tested individually in a laboratory environment. Computer-based test items (designed using Authorware Professional; Macromedia, 2003) were delivered through a laptop personal computer. The experimental procedure included a rapid computer-based diagnostic test and a paper-based test with recording of students' on-paper actions and think-aloud verbal reports. The sequence of the test administration was counterbalanced: Approximately one-half of students performed the rapid test first, and the rest performed the paper-based test first.

**Rapid diagnostic test.** The test included five tasks corresponding to the following values of angles between vectors: 0° (the same direction of movements), 180° (opposite directions of movements), 90° (perpendicular vectors), 120°, and 60°. In addition, when 60° or 120° angles were used, only equal velocity values for both vectors were allowed. Without these restrictions, the procedures for calculating the length of the resulting vectors required more advanced knowledge of trigonometry that was not a part of the assessment objective in this study. Each textual task statement was followed by five suggested solution steps (correct or incorrect) for rapid verification.

The first verification subtask for each task provided vector graphs indicating only directions of movements. The second verification subtask provided vector graphs with velocity values indicated next to them. For example, for the previously mentioned task that described a situation with perpendicular directions of movements, vector graphs indicating perpendicular directions of movements with corresponding velocity values were provided. The third verification subtask, in addition to the vectors and their values, graphically represented the vector addition operation. For example, for the fourth task ("A boat is traveling at 5 m/s. A passenger runs across the deck at 5 m/s in a direction of 120° relative to the direction of motion of the boat. What is the velocity of the passenger relative to the water?"), the third verification subtask is presented in Figure 1 (incorrect step). The fourth verification subtask provided all necessary graphical information and indicated a numerical expression for calculating the length of the resulting vector. For example, for the above (120° angle) task, a simple expression  $V = 5 \text{ m/s}$  was placed next to the diagram (60° angles and equal sides in two equilateral triangles were also indicated on the diagram). Finally, the fifth verification subtask

Figure 1. Snapshot of the rapid response window for a vector (V) addition motion task.

included final numerical answer (an integer or surd) with no graphics provided.

Students were instructed that each task in the test would be displayed for a limited time and that following each task, several possible (correct and incorrect) solution steps would be presented one at a time. The task exposure time (15 s) was established in preexperimental trials as sufficient for reading and comprehending task statements. Students were told that most of the suggested steps were possible intermediate stages on a way to the solution, but some suggested steps could also indicate final answers. For each suggested step, students had to immediately verify whether this could be a correct step leading to the solution (or providing the final answer). Each solution verification window included a diagrammatic and/or numerical representation of a possible solution step and the buttons *right*, *wrong*, and *don't know* for students to click on.

Before the rapid test, the participants were coached in responding sufficiently rapidly using exercises with simple tasks from a different area (common arithmetic calculations). During those exercises, the students got a sense of what was considered a rapid response. If a student did not respond within a set short time interval of few seconds, she or he was asked to respond faster next time and was recommended to try another exercise task. This brief procedural pretraining session was chosen instead of mechanically limiting the allowed verification response time to several seconds. The system-controlled response time (by automatically switching to the next verification window or task after a fixed short time interval) could forcefully interrupt genuine verification responses, thus invalidating results.

Each rapid diagnostic task was followed by a subjective rating of task difficulty, with a 9-point scale ranging from 1 (*extremely easy*) to 9 (*extremely difficult*) presented on the screen for students to click on. Students' response times, performance scores, difficulty ratings, and test times were automatically recorded by the software. In this experiment, the scores allocated for correct responses depended on the level of advancement of intermediate

solution stages represented in different verification subtasks. For example, the first subtask required learners to verify the application of only one step (a graphical representation of vectors), and a score of 1 was allocated for a correct response. On the other hand, the fifth subtask required learners to verify the result of the application of five sequential procedural steps, and a score of 5 was allocated for a correct response. Null scores were allocated for incorrect responses and "don't know" entries. Prior to the test, participants were instructed to enter "don't know" instead of guessing their responses any time they were in doubt. Because this was not a high-stake test, the students were expected to follow these instructions. Therefore, both incorrect responses and "don't know" entries were assumed to reflect a lack of specific knowledge, and null scores were allocated for both types of responses. The maximum possible total score for all five tasks in this test could be  $5 \times (5 + 4 + 3 + 2 + 1) = 75$ .

**Paper-based test.** Five textual task statements presented to learners were similar to those used in the rapid test (wording and numerical values in the task statements were changed). Each task statement was printed at the top of a separate page. Students were instructed to provide a complete solution for each task below the task statement as quickly as they could and think aloud while solving the task. Before commencing the procedure, participants were briefly coached in how to deliver a think-aloud protocol. The moderator (a research assistant) instructed them to think out loud at all times (e.g., "It really helps me to understand what you are thinking while solving the problem. If you get quiet, I will ask you to keep talking"). The moderator prompted participants to continue thinking aloud ("Please keep talking") every time they were silent for more than several seconds. Each diagnostic task was followed by a paper version of the subjective rating scale of task difficulty. The scale was identical to that used in the computer-based test; however, instead of clicking on their responses, students were asked to tick or circle them.

Time taken to complete the test was recorded for each participant. Students' problem-solving steps on paper as well as their verbalizations were recorded using a digital video camera. The camera was mounted on a tripod and focused on paper pages. Only the pages and students' hands were visually recorded. The research assistant collected the audiovisual performance records for each participant, and I subsequently analyzed them in order to evaluate levels of student task-specific expertise. The most important performance indicators that I looked for during this analysis were the following: search processes (if any) performed prior to executing specific solution steps, time taken by the participant before starting to carry out specific solution steps, and consistency and continuity of the solution process. For example, if the records demonstrated that a participant spent time on searching for possible moves at the beginning and/or subsequent stages of the solution process (rather than immediately applying available knowledge of relevant solution steps), her or his perceived level of expertise in this task domain was accordingly lowered.

A student's performance in each task was quantitatively assessed as the number of correct solution steps that the student had completed continuously within a short period of time (usually 10–20 s) of starting the solution. This score was determined on the basis of the analysis of both visual and audio recordings of the student's actions. The steps that were preceded by long chains of reasoning or searching and required more time did not count (even if they were eventually

completed correctly), because they were not based on immediately available knowledge of solution procedures in LTM. Thus, because five major steps were required to complete each of the five tasks, scores from 0 to 5 were allocated for a task. A total score out of 25 was assigned to each participant. The validity of this scoring method was supported by evident associations between the scores and expected levels of expertise based on participants' academic specializations: Students studying mathematics and technical subjects generally scored higher than those in nontechnical areas. For example, 11 out of 12 participants representing technical areas and only 5 out of 21 representing nontechnical areas were in the upper half (with scores above the mean).

Results and Discussion

Data for 1 student were lost because of a software problem. The variables under analysis were as follows: paper-based test time (time in seconds each learner spent on reading statements and solving all five test tasks),  $M = 476.75$ ,  $SD = 313.75$ ; rapid computer-based test time (time each learner spent on reading statements and verifying suggested steps for all five test tasks),  $M = 147.97$ ,  $SD = 20.33$ ; test scores for the traditional test,  $M = 13.12$ ,  $SD = 7.12$  (58% correct, actual range of test performance scores from 0 to 25); test scores for the rapid test,  $M = 46.19$ ,  $SD = 11.32$  (62% correct, actual range of test performance scores from 22 to 67); difficulty ratings averaged over all five tasks for the traditional test,  $M = 5.54$ ,  $SD = 2.00$  (actual range of ratings from 1.4 to 9.0; the rating 1 corresponded to extremely easy tasks); and average difficulty ratings for the rapid test,  $M = 4.68$ ,  $SD = 1.82$  (actual range of ratings from 1.0 to 8.6). Correlations between all variables are presented in Table 1.

A Pearson product-moment correlation,  $r(31) = .71$ ,  $p < .01$ , between scores for the traditional and rapid tests was obtained, with 95% confidence interval extending from 0.48 to 0.85, suggesting a high degree of the concurrent validity for the rapid test scores. A Pearson product-moment correlation between average ratings of task difficulty for the traditional and rapid tests was  $r(31) = .67$ ,  $p < .01$ , with 95% confidence interval extending from 0.42 to 0.83. There was a significant difference between test times for the traditional and rapid tests,  $t(31) = 5.90$ ,  $p < .01$ . Test time for the rapid method was reduced by a factor of 3.22 in comparison with the time for the traditional test. The average response time (in seconds) for verification subtasks was  $M = 3.04$ ,  $SD = 0.81$ , indicating that students actually responded rapidly, as they had been instructed and coached prior to the test. The estimates of Cronbach's coefficient alpha (.97 for the rapid test and .81 for the

traditional test) provided evidence of internal consistency of the scores. The high values are not surprising considering that the tasks measured closely associated attributes (a set of highly related procedural skills in solving a specific class of tasks).

As expected, difficulty ratings in both tests indicated significant negative correlations with test scores. These correlations reflect the fact that more knowledgeable learners experience lower WM load and perceive the tasks as being easier. Test times in the rapid test did not correlate with test times in the traditional test, thus indicating a qualitatively different nature of the rapid test format. The rapid test does not appear to be just an abbreviated version of the traditional diagnostic test. Nevertheless, both tests measure the same construct as indicated by the highly significant correlation between their scores. The rapid test scores did not correlate significantly with rapid test times, indicating that higher scores were likely due to immediately available knowledge base rather than longer time spent on searching for the correct response.

A negative correlation between test times and scores was expected for the traditional test: More knowledgeable learners should obviously finish earlier than less experienced students. Contrary to the expectation, a positive (although nonsignificant) correlation of .19 was obtained. The examination of video records revealed that in kinematics, the computationally intensive and very time-consuming last stage of the solution was rarely reached (or almost immediately abandoned) by novices; however, it was painstakingly performed by more experienced students, thus accounting for extended solution time for these participants.

The results of this experiment indicate highly significant correlations between learners' performance scores and difficulty ratings on the rapid verification tasks and traditional measures of learners' task-specific expertise, thus demonstrating a high degree of concurrent validity of the scores obtained from the suggested method. The rapid test was also completed much quicker than the traditional test. To further validate the rapid verification method, I applied it to a different task area in the following experiment.

Experiment 2

This experiment was designed as a correlation study in the task domain of transforming graphs of linear and quadratic functions in mathematics. Two tasks asked students to transform a provided graph of the basic line  $y = x$  into graphs of more complex lines,  $y = -2x + 3$  and  $y = \frac{1}{3}x - 2$  (see Figure 2 for an example of a task's statement). The following two tasks asked students to transform a provided graph of the basic line  $y = x^2$  into graphs of more complex quadratic functions,  $y = -\frac{1}{3}x^2$  and  $y = 2(x - 2)^2$ . The tasks required application of two or three of the following operations: flipping a graph because of the minus sign in front of  $x$  or  $x^2$  (the negative slope), squeezing (expanding) a graph toward (from) the y-axis according to the value of a coefficient in front of  $x$  or  $x^2$  (more or less than 1), and horizontal/vertical shifting. The aim of this study was to demonstrate that the rapid verification test in this task domain could be completed rapidly but that the resulting scores would have a high degree of concurrent validity.

Method

Participants

Thirty-three university students who took part in the previous study participated in this experiment. Because the task domain in

this study was completely different and unrelated to the previous experiment, using the same students could possibly not bias the results. On the contrary, it was expected that the participants' familiarity with the general format and demands of the rapid testing would eliminate its procedural novelty as a possible negative factor and increase the robustness and validity of results. In addition, the need for pretraining on the rapid testing procedure was also eliminated. In this sense, Experiment 1 could be regarded as a preliminary study in the different task domain, one of the purposes of which was to provide students with extensive pretraining in the rapid testing procedure in realistic conditions.

All students had been taught elementary mathematics in their high school courses. Such courses always include graphs of linear and quadratic functions. Some participants (especially those enrolled in nontechnical university courses) did not deal regularly with such problems and were relative novices in the task domain. Other participants (notably those studying mathematics and engineering courses) were more experienced in the domain. According to the values of total rapid test scores (the maximum possible score of 16), 3 participants were in the range from 0 to 4 (the bottom quarter), 14 participants were in the range from 5 to 8 (the second quarter), 14 participants were in the range from 9 to 12 (the third quarter), and 2 participants were in the range from 13 to 16 (the upper quarter). Students with more expected experience in the domain performed better on the experimental tasks (e.g., students studying mathematics and technical subjects generally scored higher than others in both tests). All participants had not previously encountered tasks formulated using the current format.

### Materials and Procedure

The experimental procedure was identical to that used in the previous experiment and included a rapid computer-based diagnostic test and a paper-based test with recordings of students' on-paper actions and concurrent verbal reports. The sequence of the test administration was counterbalanced.

**Rapid diagnostic test.** Each task statement was presented for 10 s (this time was established in preexperimental trials as suffi-

cient for comprehending very brief task statements) and was followed by four suggested solution steps for rapid verification. Students were instructed that most of the suggested steps were possible intermediate moves on a way to the solution, but some suggestions could also indicate final answers. Figure 3 shows an example of an incorrect intermediate step for the task represented in Figure 2. Some verification subtasks indicated results of the application of only one operation, whereas other subtasks indicated results of the application of several operations (e.g., flipping and expanding in Figure 3).

Because of the nature of the task, the scoring procedure in this study was different from the cumulative scoring approach used in the previous experiment. For the vector addition tasks, verification subtasks for each solution stage, except the final numerical answer, showed explicitly the fixed cumulative sequence of all prior steps that students would normally perform. For example, a diagram representing the graphical addition of vectors would necessarily show the vectors themselves with assigned numerical values (the essential attributes of the previous solution steps). In contrast, for the tasks used in this experiment, verification subtasks showed only results of the application of an ordered set of possible prior steps. An individual student might not necessarily solve the task using this specific sequence of steps. For example, when constructing a graph of the line  $y = -2x + 3$ , one person could first flip the line  $y = x$ , then squeeze the flipped line, followed by the shifting of the squeezed line up. Another individual would prefer to squeeze the original line first, then shift the squeezed line, and finish by flipping the shifted line. Yet another student would shift first and then perform one of the two possible sequences of the remaining steps.

As a result, in this task domain, the verification process is likely to be performed by locating a feature that would immediately

Figure 3. Snapshot of the rapid response window for a graph transformation task.

exclude the suggested step from a list of possible correct steps rather than by comparing the suggested step with different progressive stages of a mentally constructed solution sequence. For example, noticing that a flipped line is depicted for a function with a positive slope, or that an expanded line is depicted when the squeezing operation is required, or that a shift is made in the wrong direction would immediately flag an incorrect step. Because locating a single incorrect operation could be sufficient for the verification purpose, the scoring procedure in this task domain allocated a score of 1 for each correctly performed verification subtask. Therefore, the maximum possible score in the rapid test (4 tasks with 4 verification subtasks for each task) was  $4 \times 4 = 16$ . Each diagnostic task was followed by a 9-point subjective rating scale of task difficulty. Students' performance scores, difficulty ratings, and test times were automatically recorded by the software.

*Paper-based test.* Task statements presented to learners were similar to those used in the rapid test (numerical values in the task statements were changed). Students were asked to provide a complete solution for each task and think aloud while solving the task. A blank coordinate plane was provided on each of the four pages underneath the task statement. Students' problem-solving steps on paper and their concurrent verbalizations were recorded using a digital video camera. Each diagnostic task was followed by a paper version of the subjective rating scale. A student's performance on each task was scored as the number of correct steps that the student completed continuously within a short period of time (10–20 s) of starting the solution, based on the analysis of both visual and audio recordings of her or his actions. A total score out of 9 was allocated to each participant (for one task, the range of scores was from 0 to 3; for the remaining three tasks, the ranges were from 0 to 2). The adequacy of this scoring method was backed by clear associations between the scores and expected levels of expertise based on participants' academic specializations (students studying nontechnical subjects generally scored lower than those studying technical domains). For example, all 12 participants representing technical areas and only 3 out of 21 representing nontechnical areas were in the upper half (with scores above the mean).

### Results and Discussion

The variables under analysis were paper-based test time (time in seconds each learner spent on solving all four test tasks),  $M = 371.27$ ,  $SD = 193.71$ ; rapid computer-based test time (time each learner spent on solving all four test tasks),  $M = 105.52$ ,  $SD = 19.99$ ; test scores for the traditional test,  $M = 3.30$ ,  $SD = 2.85$  (37% correct, actual range of test performance scores from 0 to 9); test scores for the rapid test,  $M = 8.33$ ,  $SD = 2.77$  (52% correct, actual range of test performance scores from 2 to 15); average difficulty ratings for the traditional test,  $M = 3.63$ ,  $SD = 1.82$  (actual range of ratings from 1 to 7); and average difficulty ratings for the rapid test,  $M = 4.05$ ,  $SD = 1.83$  (actual range of ratings from 1 to 7.75). Correlations between all variables are presented in Table 2.

A Pearson product-moment correlation,  $r(32) = .75$ ,  $p < .01$ , between scores for the traditional and rapid tests was obtained, with 95% confidence interval extending from 0.55 to 0.87, suggesting a high degree of the concurrent validity for the rapid test scores. A Pearson product-moment correlation between average ratings of task difficulty for the traditional and rapid tests was  $r(32) = .82$ ,  $p < .01$ , with 95% confidence interval extending from

Table 2.  
*Correlations for Variables in Experiment 2*

Variable	1	2	3	4	5	6
1. Rapid test scores	–	.75**	–.55**	–.53**	–.23	–.40*
2. Traditional test scores		–	–.39*	–.47**	–.33	–.45**
3. Rapid test difficulty			–	.82**	.41*	.12
4. Traditional test difficulty				–	.43*	.22
5. Rapid test time					–	.16
6. Traditional test time						–

\* $p < .05$ . \*\* $p < .01$ .

0.66 to 0.91. There was a significant difference between test times for the traditional and rapid tests,  $t(32) = 7.97$ ,  $p < .01$ . Test time for the rapid method was reduced by a factor of 3.52 in comparison with the time for the traditional test. It should be noted that when the results of the rapid test in this experiment were rescored using a cumulative scoring procedure, similar to that used in Experiment 1, a nonsignificant Pearson product-moment correlation,  $r(32) = .21$ ,  $p = .25$ , was obtained between scores for the traditional and rapid tests. This significantly lower correlation value than that obtained using a simple scoring method indicates that the selection of an adequate scoring method is essential.

As in Experiment 1, there were significant negative correlations between difficulty ratings and test scores in both tests. These correlations reflect decreased WM load with increased levels of learner expertise. Test times in the rapid test did not correlate with test times in the traditional test, thus indicating a different nature of the rapid test format. As expected, rapid test scores did not correlate with rapid test times, and traditional test scores negatively correlated with traditional test times (less knowledgeable learners required more time to complete the test). The estimates of Cronbach's coefficient alpha (.96 for the rapid test scores and .85 for the traditional test scores) provided evidence that the reliability (internal consistency) of the test scores was very high.

Thus, significant correlations between performance scores as well as difficulty ratings obtained using rapid test tasks and traditional measures of expertise in this experiment demonstrated a high degree of concurrent validity of the rapid verification scores. The rapid test was also completed significantly quicker than the traditional test.

### General Discussion

Rapidly measuring levels of learner task-specific expertise is required for adapting instructional techniques and formats to changing levels of learner proficiency dynamically, in real time. The experiments described in this article were aimed at validating a rapid verification method for diagnosing levels of learner task-specific expertise. Students were presented with a series of possible (correct and incorrect) intermediate steps of a task solution and were asked to rapidly verify each step (i.e., to establish whether the suggested step was correct). Two experiments were designed to evaluate the concurrent validity of the rapid verification scores in two different task domains. Experimental data obtained from university students in task domains of vector addition problems in kinematics and graph transformation tasks in mathematics indicated significant correlations (correspondingly, .71 and .75) be-

tween performance scores on rapid verification tests and measures of expertise that were based on observations of students' detailed solutions of similar tasks. Rapid test times were reduced by factors of 3.2 (for kinematics tasks) and 3.5 (for mathematics tasks) in comparison with traditional test times. Thus, the results indicate that suggested tests could be completed rapidly and that their scores have a high degree of concurrent validity.

Values of Cronbach's coefficient alpha (.97 and .96) provided evidence that the reliability (internal consistency) of the rapid test scores in both experiments was sufficiently high. Task difficulty ratings and test times were used to obtain additional indications of validity of the rapid tests. As expected, task difficulty ratings correlated negatively with test scores in both experiments: Tasks were relatively easier for more expert learners (as measured by the suggested rapid test) than for less experienced participants. In rapid tests in both experiments, there were no correlations between test times and scores, indicating that participants' responses were likely based on their immediately available knowledge structures rather than on time-dependent search processes.

In both experiments, test times in the rapid tests did not correlate with test times in the corresponding traditional tests. This result provides an additional indication that rapid verification tests represent a qualitatively different diagnostic assessment format and not just abridged versions of the corresponding traditional tests. It could be assumed that rapid verification tasks involved a different set of cognitive processes than traditional tests (e.g., searching for a suggested verification solution step in the mentally constructed solution procedure for a task or searching for a feature that would immediately exclude a suggested step from possible correct steps).

Participants in this study ranged from undergraduate to postgraduate university students. As noted by one of the reviewers, the assumption was that each student can be ranked with respect to expertise. There could be a potential confound due to different student abilities: Individuals who finish a graduate school may be brighter than undergraduates in general. However, according to one of the cognitive sciences most important and established results, the level of expertise associated with the available knowledge base is the most important factor influencing student learning and performance, and in most situations, it would override other relevant factors.

Thus, in response to the three research questions formulated for this empirical study, it is possible to state that (a) the suggested online verification procedure is a valid diagnostic method capable of detecting different levels of acquisition of domain-specific knowledge structures, (b) the suggested online verification procedure is a rapid method that could be completed fast enough for real-time applications, and (c) the suggested rapid verification procedure is likely to generalize to different task domains. The rapid verification method, as well as the previously investigated first-step method (Kalyuga & Sweller, 2004), are capable of providing evidence about learner levels of expertise that is diagnostically more valuable and powerful than that obtained in traditional (e.g., multiple-choice) tests. The value of this evidence may approach that of verbal reports, however, with testing times significantly reduced compared with alternative assessment methods.

Applying the rapid verification method to a task generally includes the following steps: (a) establish a sequence of possible main intermediate stages in the solution procedure for the task; (b) for each stage, select representative (either correct or incorrect)

solution steps; (c) present the original task statement to a learner for a limited time sufficient to read and understand the statement; (d) present a series of the selected intermediate solution steps to learners, one at a time, with the requirement to quickly verify whether each of the suggested steps could lead to a complete solution of the task; (e) select a scoring method depending on the uniqueness of the solution sequence for the task. If there is only one possible solution path, use a cumulative scoring method (allocate higher scores for more advanced steps that are verified correctly, with one unit added to the score for each level of advancement). If there is a range of possible solution paths, use a simple scoring method (a score of 1 is assigned for each correctly verified step).

For example, in the class of simple linear equations of the type  $ax + b = c$  (solve for  $x$ ), two main solution stages are subtracting  $b$  from both sides of the equation and dividing both sides of the resulting equation by  $a$ . Therefore, for the representative task  $3x + 2 = 5$  (solve for  $x$ ), the first step in the design of the rapid verification test is establishing sequential stages of the solution procedure:  $3x + 2 - 2 = 5 - 2$ ;  $3x = 3$ ;  $3x/3 = 3/3$ ; and  $x = 1$ . At the second step, representative solution steps could be selected, for example,  $3x + 2 - 5 = 5 - 5$  (incorrect);  $3x = 3$  (correct);  $3x/5 = 3/5$  (incorrect);  $x = 2$  (incorrect). Then, the original task statement should be presented to a learner for a few seconds followed by the selected representative solution steps, one at a time. The learner should quickly determine whether the suggested steps could lead to a complete solution of the task. Finally, because there is only one possible solution path in this case, a cumulative scoring procedure needs to be applied. Scores of 4 or 3 should be allocated, respectively, for verifying rapidly the suggested final answer or the step immediately preceding it (in the provided example,  $x = 2$  and  $3x/5 = 3/5$ , respectively). A score of 2 should be allocated for a correct answer at the stage of completed application of the first procedural step ( $3x = 3$ ) and a score of 1 for verifying an incomplete intermediate step in the application of the first step ( $3x + 2 - 5 = 5 - 5$ ).

This study has been limited to two task classes associated with sufficiently well-structured tasks and predictable solution paths. In such areas, different levels of expert behavior could be described as sequential solution stages a person can complete immediately on starting the solution process. More ambiguous and poorly specified task domains, for example, areas that involve problems with multiple possible routes to solutions, may require special content validation procedures in order to establish expertlike solution paths. The rapid verification method could possibly be used in such relatively poorly structured task domains. Only a limited number of situations or steps representing different possible stages of valid solution procedures could be selected and included into rapid verification subtasks. For example, for a medical diagnosis task, a sequence of progressively more advanced stages of testing different hypotheses (including both suitable and inappropriate steps) could be presented for rapid verification. Because of the variety of possible solution paths in this case, a simple scoring procedure should be applied. In further research, the generality and limits of usability of the method, especially in poorly structured task domains, need to be established.

In some areas, the rapid assessment approach (both the first-step and rapid verification methods) could be more suitable for measuring level of expertise of relatively advanced learners rather than

for thorough cognitive diagnosis of novices. Novice learners may have knowledge deficits of types that could not be anticipated in advance when selecting relevant possible solution steps for verification or programming the scoring engine (e.g., linguistic comprehension problems, insufficient factual knowledge, lack of basic metacognitive planning and monitoring skills). Most of these types of knowledge are usually taken for granted when dealing with relatively more experienced learners.

As a form of dynamic assessment, the method could be instrumental in developing adaptive expertise (Bransford et al., 1999) by enabling the selection of optimal environments for building flexible skills. On the basis of the fine-grained diagnosis of the acquired knowledge and skills in a task domain, such environments would provide learners with individually tailored instructional support that is optimal for moving on to the next level of expert performance. Acquisition of task-specific expertise is necessary for releasing cognitive resources for dealing with more nonroutine and creative aspects of expert performance. With learner-tailored, just-in-time forms of support, learners would be capable of efficiently handling relatively new situations without a cognitive overload and associated loss of interest in the task.

A preliminary study indicated that the suggested diagnostic method could be successfully used for the dynamic selection of appropriate levels of instructional guidance that are optimal for learners with different levels of task-specific expertise (Kalyuga, 2006a). The method was used in an adaptive tutorial in the domain of kinematics for online monitoring of current levels of learner expertise. At the beginning of a tutoring session, each student was allocated to an appropriate level of guidance according to the outcome of the initial rapid verification test. Depending on the outcomes of rapid verification probes during instruction, the learner was allowed to proceed to the next stage or required to repeat the same stage and then take the rapid test again. At each subsequent stage, a lower level of instructional guidance was provided to learners by gradually fading fully worked-out steps and increasing the number of steps that learners had to complete on their own. Also, a higher level of the rapid verification task was used at the end of the stage. The adaptive approach proved to be superior to traditional nonadapted instructional formats. In the future, more comprehensive studies are needed for comparing different dynamic adaptive methodologies based on rapid diagnostic techniques. Optimized adaptive learning environments need to be developed and tested in relatively more complex and less structured domains than tasks in mathematics and kinematics.

Researchers' knowledge of cognitive processes in learning and problem solving has advanced substantially, and many cognitively supported instructional methods have been developed. Efficient tailoring of these instructional methods to learners with different levels of task-specific expertise is dependent on researchers' ability to rapidly and accurately measure these levels of expertise in real time. This article is intended as a step in developing such rapid online diagnostic methods.

# On the Measurement of Achievement Goals: Critique, Illustration, and Application

Andrew J. Elliot  
University of Rochester

Kou Murayama  
Tokyo Institute of Technology

The authors identified several specific problems with the measurement of achievement goals in the current literature and illustrated these problems, focusing primarily on A. J. Elliot and H. A. McGregor's (2001) Achievement Goal Questionnaire (AGQ). They attended to these problems by creating the AGQ-Revised and conducting a study that examined the measure's structural validity and predictive utility with 229 (76 male, 150 female, 3 unspecified) undergraduates. The hypothesized factor and dimensional structures of the measure were confirmed and shown to be superior to a host of alternatives. The predictions were nearly uniformly supported with regard to both the antecedents (need for achievement and fear of failure) and consequences (intrinsic motivation and exam performance) of the 4 achievement goals. In discussing their work, the authors highlight the importance and value of additional precision in the area of achievement goal measurement.

*Keywords:* goal, performance, mastery, approach, avoidance

For the past two decades, achievement goals have been a central construct in the study of motivation in achievement settings. Some achievement goal research has been experimental in nature, manipulating goals and examining their effect on outcomes relevant to achievement. However, the vast majority of achievement goal research has been correlational, measuring preexisting goals and examining the antecedents and consequences of these goals in concurrent, prospective, and occasionally longitudinal designs. Both the experimental and the correlational research have yielded a substantial amount of information about the strivings of individuals (most commonly students, athletes, and employees) in achievement contexts and the implications of these strivings (see Duda, 2005; Elliot, 2005; Meece, Anderman, & Anderman, 2006; Payne, Youngcourt, & Beaubien, 2007; Ryan, Ryan, Arbuthnot, & Samuels, 2007). Beyond doubt, the achievement goal construct represents a landmark contribution to the century-long study of competence and motivation.

Although clearly informative and generative, the achievement goal approach also faces its share of challenges and difficulties. Perhaps foremost among these challenges and difficulties is a long-term struggle to assess achievement goals in a conceptually rigorous manner. Some achievement goal measures rest on a weak

foundation in that the achievement goal concept is not clearly articulated a priori, thereby providing little guidance for how goals should be operationalized. Even when a clear conceptualization of achievement goals is in place, however, there is often poor correspondence between how the goals are conceptualized and how they are operationalized. This poor correspondence is of great consequence, because it makes it difficult to interpret empirical results straightforwardly and confidently, whether they are supportive or unsupportive of theoretical predictions. Interpretational ambiguity, in turn, retards theoretical progress in the achievement goal literature and undermines attempts to transfer information gleaned from research to real-world achievement settings.

In the present article, we identify several specific problems with the measurement of achievement goals in the current literature. We focus primarily on one achievement goal measure—Elliot and McGregor's (2001) Achievement Goal Questionnaire (AGQ)—to explicate and illustrate these problems. We begin by describing the conceptual foundation from which the AGQ emerged. We then show different ways in which particular AGQ items do not optimally correspond to this conceptual foundation and describe how such problems may be rectified. We also point to other examples in the achievement goal literature to demonstrate that these problems are not unique to the AGQ. The result of critiquing and adjusting the AGQ is a new achievement goal measure, the AGQ-Revised (AGQ-R), which we proceed to empirically test. Specifically, we examine the structural validity of the measure using both established and novel procedures and report data on the predictive utility of the goal subscales from this measure. Our aim is to demonstrate that the problems with existing achievement goal measures can be rectified while retaining (and perhaps, in some instances, even enhancing) the reliability and validity of the original measures.

## Conceptual Foundation

Elliot and McGregor's (2001) AGQ was designed to assess achievement goals as conceptualized in the  $2 \times 2$  achievement

goal framework (Elliot, 1999; Elliot & McGregor, 2001) within the hierarchical model of approach–avoidance achievement motivation (Elliot, 1997, 2006). From this perspective, achievement goals are conceptualized as cognitive–dynamic aims that focus on competence, and any given achievement goal is thought to contain components from two independent competence dimensions. The *definition* dimension forms the basis of a mastery–performance distinction, which has been a part of the achievement goal tradition since its inception (Maehr & Nicholls, 1980). Competence may be defined in terms of the standard used to evaluate it, that is, relative to an absolute or intrapersonal standard (mastery) or relative to a normative standard (performance). Mastery-based standards tend to focus individuals on learning, whereas performance-based standards tend to focus individuals on performing (Dweck, 1986). The *valence* dimension of competence forms the basis of an approach–avoidance distinction, a later addition to the achievement goal tradition (Elliot & Harackiewicz, 1996). Competence may be valenced in terms of whether it is focused on a positive possibility to approach (i.e., success) or a negative possibility to avoid (i.e., failure). Combining the mastery–performance and approach–avoidance distinctions leads to four different types of achievement goals: mastery–approach (focused on attaining task-based or intrapersonal competence), performance–approach (focused on attaining normative competence), mastery–avoidance (focused on avoiding task-based or intrapersonal incompetence), and performance–avoidance (focused on avoiding normative incompetence).

When viewed from a hierarchical standpoint (see Elliot, 2006), the achievement goals of the  $2 \times 2$  framework are posited to emerge from more general motivations (e.g., the need for achievement and fear of failure), self-conceptions and theories (e.g., entity and incremental theories of ability), and environmental emphases (e.g., classroom goal structures). These goals are viewed as the proximal predictors of important achievement-relevant outcomes such as intrinsic motivation and performance attainment (Elliot & Church, 1997).

### Problems in Achievement Goal Measures

A host of achievement goal measures have appeared in the educational psychology, industrial–organizational psychology, social-personality psychology, and sport and exercise psychology disciplines over the past two decades, some of which have focused on the mastery–performance distinction alone, and others of which, like the AGQ, have focused on both the mastery–performance and approach–avoidance distinctions. In the following, we identify a number of problems that have appeared in these measures. We do so using the AGQ in illustrative fashion, as the focal point of both critique and solution.<sup>1</sup>

#### *Failing to Assess Goals*

In the  $2 \times 2$  framework, *goal* is conceptualized as an aim that one is committed to that serves as a guide for future behavior (Elliot, 1999; Elliot & Fryer, 2008). However, the prefixes of some AGQ items seem to suggest a value (e.g., “It is important for me to do better than other students”) or a concern (e.g., “I worry that I may not learn all that I possibly could in this class”), rather than a goal per se. Our solution to this problem is to select the same set of three prefixes for each goal scale in the AGQ-R, each of which

is exclusively goal-based (“My goal is to . . .,” “My aim is to . . .,” and “I am striving to . . .”).

Most achievement goals theorists would likely agree that achievement goals are best construed in terms of purposeful commitments that guide future behavior (Dweck & Elliott, 1983; Maehr, 1989). Nevertheless, taken at face value, many goal items do not seem to be temporally focused and do not appear to assess intentional commitments. Some items ask respondents to report on how they define success (e.g., “I feel most successful when . . .”; Button, Mathieu, & Zajac, 1996; Duda, Chi, Newton, Walling, & Catley, 1995; Duda & Nicholls, 1992; Midgley et al., 2000 [original]; Nicholls, Cobb, Wood, Yackel, & Patashnick, 1990; Nicholls, Patashnick, & Nolen, 1985; Roberts & Treasure, 1995; Roedel, Schraw, & Plake, 1994; Skaalvik, 1997). Others ask respondents to report on their values or concerns (e.g., “I value . . .”; Bouffard, Boisvert, Vezeau, & Larouche, 1995; Button et al., 1996; Conroy, Elliot, & Hofer, 2003; Elliot & Church, 1997; Harackiewicz, Barron, Elliot, Carter, & Lehto, 1997; Meece, Blumenfeld, & Hoyle, 1988; Middleton & Midgley, 1997; Midgley et al., 2000 [original and revised]; Roedel et al., 1994; Skaalvik, 1997; Stipek & Gralinski, 1996; VandeWalle, 1997; Zweig & Webster, 2004). Finally, others ask respondents to indicate what they like or prefer, or are pleased or satisfied by (e.g., “I feel really pleased when . . .”; Bouffard et al., 1995; Button et al., 1996; Elliot & Church, 1997; Harackiewicz et al., 1997; Middleton & Midgley, 1997; Midgley et al., 2000 [original]; Roedel et al., 1994; Skaalvik, 1997; Stipek & Gralinski, 1996; VandeWalle, 1997; Zweig & Webster, 2004). Although such items may capture goal adoption or lead to goal pursuit, more direct and precise wording is clearly both possible and desirable.

#### *Collapsing Together the Goal and the Motivation Underlying the Goal*

In the  $2 \times 2$  framework, a goal is construed as a cognitively represented aim, and this aim is viewed as separate from the reason or reasons why the person is pursuing the aim (Elliot & Thrash, 2001). As such, mastery-based and performance-based goals are differentiated with regard to the specific type of competence (incompetence) that one seeks to approach or avoid, and any additional reasons for such striving are excluded from the goal construct per se. From this standpoint, it is best to assess the reason behind the goal separately from the goal itself, thereby allowing the possibility of numerous achievement goal “complexes” (i.e., goal–reason combinations; see Elliot & Thrash, 2001, and Thrash & Elliot, 2001, for a discussion of the benefits of keeping goals conceptually separate from reasons). In the AGQ, however, one of the performance–avoidance goal items collapses the goal together

<sup>1</sup> Our review of other achievement goal measures is meant to be broad in scope but not comprehensive. The measures that we focus on herein are published in highly visible journals, have been widely used in the achievement goal literature, or contain items that are particularly fine examples of the points we seek to highlight. Some of these measures are currently used in achievement goal research, whereas others are no longer used (although data from these measures continue to be used to support conceptual points in the literature). It should be noted that not all measures that are cited together in the text within any given point necessarily share the same theoretical perspective.

with an underlying motive, fear of failure: "My fear of performing poorly in this class is often what motivates me"; indeed, it focuses more on the motive than the goal. Our solution to this problem is to omit the motive content in the AGQ-R version of this item, thus allowing fear of failure to be assessed separately and the link between fear of failure and performance-avoidance goals to be examined without item overlap.

Our view of goal as "aim separate from reason" is consistent with most conceptualizations of the goal construct in scientific psychology (Elliot & Fryer, 2008), but is different from the way that many, if not most, achievement goal theorists construe goals. Achievement goal theorists tend to prefer a combined aim-reason goal construct (Ames, 1992; Pintrich & Schunk, 1996); thus, items that combine aim and reason clearly would not be considered a problem for such theorists. Indeed, performance-based goal measures commonly include item content involving demonstrating or showing something to others, as well as a focus on normative competence (Button et al., 1996; Elliot & Church, 1997; Greene & Miller, 1996; Harackiewicz et al., 1997; Meece et al., 1988; Midgley et al., 2000 [revised]; Nicholls et al., 1985; Roberts & Treasure, 1995; Roedel et al., 1994; Skaalvik, 1997; Stipek & Gralinski, 1996). Some performance-based goal scales even focus on demonstration to the exclusion of normative competence (Middleton & Midgley, 1997; Midgley et al., 2000 [original]; VandeWalle, 1997; Zweig & Webster, 2004). Furthermore, in some measures, the performance-approach goal scale contains no or little mention of demonstration, whereas the performance-avoidance goal scale focuses exclusively or nearly exclusively on demonstration (Middleton & Midgley, 1997; Midgley et al., 2000 [original]; Skaalvik, 1997). In another measure, the performance-approach goal scale focuses exclusively on demonstration, whereas the performance-avoidance goal scale makes no mention of demonstration (Zweig & Webster, 2004). If reasons are accepted as part of a goal construct, it seems optimal for corresponding goal measures to balance the degree to which a focal reason, such as demonstration, is present in the two types of performance-based goals.

#### *Item Content Applicable to Both Mastery-Based and Performance-Based Goals*

In the  $2 \times 2$  framework, mastery-based and performance-based goals are differentiated in terms of their competence foci. In the AGQ, one performance-approach goal item contains content regarding grades: "My goal is to get a better grade than most of the other students." Grades can be applicable to either mastery-based or performance-based goals, depending on the nature of performance evaluation in the achievement setting (e.g., a task-based or normative grading structure). Our solution to this problem is to simply omit the reference to grades in this item in the AGQ-R.

Most achievement goal theorists would agree that mastery-based and performance-based goals focus on different types of competence (Dweck, 1986; Nicholls, 1989), but measures commonly contain content that seems applicable to both types of competence. For example, as with the aforementioned AGQ item, grades are commonly mentioned in performance-approach goal items (Bouffard et al., 1995; Dweck, 1999; Elliot & Church, 1997; Harackiewicz et al., 1997; Roedel et al., 1994). Mastery-approach goal items sometimes include content assessing the degree to

which the individual keeps busy (Nicholls et al., 1985, 1990), works hard (Duda et al., 1995; Duda & Nicholls, 1992; Nicholls et al., 1985, 1990; Roberts & Treasure, 1995), perseveres (Roedel et al., 1994), or reaches a goal (Roberts & Treasure, 1995); each of these characteristics is relevant to performance-based, as well as mastery-based, goals.

#### *Pitting One Goal Against Another*

In the  $2 \times 2$  framework, achievement goals are not presumed to be negatively correlated but instead are expected to be positively correlated (when they share a dimension) or uncorrelated (when they do not share a dimension). Accordingly, achievement goals of various types may be pursued at the same time, and it is best to assess each goal separately from the others. In the AGQ, however, one of the performance-avoidance goal items uses the word *just* ("I just want to avoid doing poorly in this class") to subtly imply the exclusion of other goals. Our solution to this problem is to simply omit this subtle reference to exclusivity in the AGQ-R items.

Some achievement goal theorists explicitly embrace the possibility of multiple goal pursuit (Barron & Harackiewicz, 2001; Pintrich, 2000), and even theorists who emphasize the possibility of performance-approach goals driving out mastery-approach goals do not portray these goals, or any others, as strongly negatively correlated in most achievement settings (see Midgley, Kaplan, & Middleton, 2001, p. 83). Nevertheless, several achievement goal measures include items that play off one goal against another. For example, in the item "Although I hate to admit it, I sometimes would rather do well in a class than learn a lot" (Dweck, 1999, p. 185) the respondent is asked to choose between a mastery-approach goal and an implicit performance-approach goal. In other measures, certain items put goals in competition with each other in a more subtle fashion (e.g., "I like it best when something I learn makes me want to find out more," Harackiewicz et al., 1997, p. 319; see also Elliot & Church, 1997; Middleton & Midgley, 1997; VandeWalle, 1997). There is certainly room for measures that focus on contrasting or rank ordering achievement goals, but it is important that these measures be explicitly identified as such and that they be used with full awareness of their limitations regarding multiple goal adoption (see Van Yperen, 2006, for an example of such a measure).

#### *Performance-Approach and Performance-Avoidance Goals That Differentially Emphasize Normative Comparison*

In the  $2 \times 2$  framework, normative comparison is an integral feature of performance-based goals. In the AGQ, the performance-approach goal items are explicitly normative in content, whereas the performance-avoidance goal items do not make specific mention of normative comparison (e.g., "My goal in this class is to avoid performing poorly"). Although it is likely that normative comparison would be implicitly read into most of these performance-avoidance goal items in most achievement contexts, it is clearly best to make the explicitness of normative comparison comparable across the two performance-based goals. As such, explicit normative content is added to each of the performance-avoidance goal items in the AGQ-R.

Most achievement goal theorists would concur that normative comparison and performance-based goals are closely connected (Maehr, 1983; Nicholls, 1984). Nevertheless, in some achievement goal measures, explicit normative content is either missing from performance-approach or performance-avoidance goals altogether (Elliot & Church, 1997; Middleton & Midgley, 1997; Midgley et al., 2000 [original]; VandeWalle, 1997) or there is an unequal proportion of normatively focused items in the two types of performance-based goals (Midgley et al., 2000 [revised]; Skaalvik, 1997; Zweig & Webster, 2004).

### *Performance-Approach and Performance-Avoidance Goals That Focus on Extreme Groups*

In the  $2 \times 2$  framework, performance-approach and performance-avoidance goals are presumed to be applicable across levels of perceived competence. Perceived competence is viewed as an important antecedent of these goals, but these relations are of moderate strength. As such, although high perceived competence tends to promote performance-approach goals, those with low and moderate perceived competence may also strive to do well relative to others; likewise, although low perceived competence tends to evoke performance-avoidance goals, those with high and moderate perceived competence may also strive to avoid doing poorly relative to others. It is possible for performance-based goal items to make high or low normative performance salient in a general way, without highlighting extremes (e.g., “do better than others” or “not do worse than others”); the more general the normative referent, the more likely the items will be to assess differences in valence per se, rather than differences in valence coupled with differences in perceived competence. In the AGQ, however, the word *most* in the performance-approach goal item, “My goal in this class is to get a better grade than most of the other students,” unnecessarily highlights a specific portion of the normative distribution. Our solution to this problem is to simply omit this qualifier in the AGQ-R item.

We are not aware of any achievement goal theorist who would espouse restricting the focus of performance-based goals to extreme groups. Nevertheless, in some achievement goal measures, performance-based goal items focus respondents on extremes in the normative distribution—specifically, being one of the best performers for performance-approach goals or not being one of the worst performers for performance-avoidance goals (Conroy et al., 2003; Elliot & Church, 1997; Middleton & Midgley, 1997; Midgley et al., 2000 [original]; Skaalvik, 1997).

### *Mastery-Approach/Mastery-Avoidance and Performance-Approach/Performance-Avoidance Goals That Contain Differential Amounts of Affective Content*

In the  $2 \times 2$  framework, affect is implied whenever any sort of goal commitment is present because this commitment represents an affective investment of the self with regard to a future possibility (Custers & Aarts, 2005; Elliot & Fryer, 2008). However, affect per se is not the central focus of the goal construct, and therefore it would be ideal if achievement goal items either were devoid of specific affective reference or, at minimum, distributed such references equally across the different types of goals. In the AGQ, the prefix of some of the mastery-avoidance goal items

contains specific affective content (e.g., “I’m afraid . . .”), whereas this is not the case for the mastery-approach goal items; likewise, one of the performance-avoidance goal items contains specific affective content (“My fear of performing poorly in this class is often what motivates me”), but none of the performance-approach goal items contain such content. Our solution to this problem is to omit explicit reference to affective content from the goal items altogether in the AGQ-R.

Some achievement goal theorists may be open to incorporating specific affective content in achievement goal items, but none would suggest that the amount of such content should vary across goals. Nevertheless, such variation is present in some measures for mastery-approach and mastery-avoidance goals (Conroy et al., 2003), as well as for performance-approach and performance-avoidance goals (Elliot & Church, 1997; Middleton & Midgley, 1997; Midgley et al., 2000 [original]; Skaalvik, 1997; Zweig & Webster, 2004).

Table 1 provides the items for the AGQ-R and pairs each revised item with the original AGQ item that it is meant to replace. This revised measure is designed to assess, in face valid fashion, the four goals of the  $2 \times 2$  achievement goal model while taking care to attend to each of the potential pitfalls that we have identified. We do not hold up the revised measure as the end of the measurement development process. Rather, we see it as an important step toward enhanced rigor and precision in an ongoing process. Furthermore, our critique of the AGQ and existing achievement goal measures is not meant to invalidate these measures or the empirical work that has been produced with them. Despite the aforementioned issues, we think that these measures have for the most part done a reasonably good job of assessing achievement goals and that the achievement goal literature has progressed accordingly. However, we do think that there is room for improvement in the area of measurement and that improvement on this front will both strengthen the empirical base of the achievement goal literature and enhance the prospects for successful application of achievement goal findings to actual achievement settings.

### *Examining the Structure and Predictive Utility of the AGQ-R*

The empirical component of the present research involved testing whether an achievement goal measure that takes into account the aforementioned measurement problems can exhibit good structural validity and have good predictive utility. Accordingly, we examined the factor structure of the AGQ-R using standard confirmatory factor analytic techniques and compared the proposed four-factor model to a series of alternative three- and two-factor models (see Conroy et al., 2003; Elliot & McGregor, 2001). We also examined whether the hypothesized four-factor model was influenced by response bias, which could produce results that appear supportive but in actuality represent artifacts (see Podsakoff, MacKenzie, Lee, & Podsakoff, 2003), and whether inclusion of the same prefixes across goal scales distorted the factor structure of the goals. Most important, we moved beyond the analysis of factor structure to an analysis of dimensional structure, testing for the first time the hypothesis that the four goals represent combinations of two underlying dimensions. This hypothesized model was also compared to alternative dimensional models. Our

Table 1  
*Items for the Achievement Goal Questionnaire-Revised (AGQ-R) Paired With the Original Achievement Goal Questionnaire (AGQ) Items*

Item	Item content
Mastery-approach goal items	
1	My aim is to completely master the material presented in this class. (original Item 9: I desire to completely master the material presented in this class.)
7	I am striving to understand the content of this course as thoroughly as possible. (original Item 8: It is important for me to understand the content of this course as thoroughly as possible.)
3	My goal is to learn as much as possible. (original Item 7: I want to learn as much as possible from this class.)
Mastery-avoidance goal items	
5	My aim is to avoid learning less than I possibly could. (original Item 4: I worry that I may not learn all that I possibly could in this class.)
11	I am striving to avoid an incomplete understanding of the course material. (original Item 5: Sometimes I'm afraid that I may not understand the content of this class as thoroughly as I'd like).
9	My goal is to avoid learning less than it is possible to learn. (original Item 6: I am often concerned that I may not learn all that there is to learn in this class.)
Performance-approach goal items	
4	My aim is to perform well relative to other students. (original Item 3: My goal in this class is to get a better grade than most of the other students.)
2	I am striving to do well compared to other students. (original Item 2: It is important for me to do well compared to others in this class.)
8	My goal is to perform better than the other students. (original Item 1: It is important for me to do better than other students.)
Performance-avoidance goal items	
12	My aim is to avoid doing worse than other students. (original Item 10: I just want to avoid doing poorly in this class.)
10	I am striving to avoid performing worse than others. (original Item 12: My fear of performing poorly in this class is often what motivates me.)
6	My goal is to avoid performing poorly compared to others. (original Item 11: My goal in this class is to avoid performing poorly.)

*Note.* Original AGQ items are from "A  $2 \times 2$  achievement goal framework," by A. J. Elliot and H. A. McGregor, 2001, *Journal of Personality and Social Psychology*, 80, 501–519. Copyright 2001 by the American Psychological Association.

predictions regarding the structure of the AGQ-R were that the 12 items would represent four separable achievement goals emerging from two independent underlying dimensions and that the hypothesized factorial and dimensional structures would prove superior to all alternatives.

An additional aim of our research was to test the new achievement goal measure within the context of the hierarchical model of approach-avoidance achievement motivation. That is, we examined achievement motives as antecedents of achievement goals and the achievement goals as proximal predictors of achievement-relevant outcomes. With regard to the antecedents of achievement goals, achievement motives—the need for achievement and fear of failure—are general, affectively based orientations toward competence presumed to be rooted in early childhood experience (Birney, Burdick, & Teevan, 1969; McClelland, Atkinson, Clark, & Lowell, 1953). We hypothesized that need for achievement would positively predict mastery-approach and performance-approach goals (Tanaka & Yamauchi, 2001; VandeWalle, 1997; Zusho, Pintrich, & Cortina, 2005). Once negative affect is removed from the mastery-avoidance goal items, need for achievement may positively predict these goals as well, although we offer this hypothesis tentatively. Avoiding errors and mistakes is sometimes a necessary component of successfully accomplishing a task; therefore, individuals high in need for achieve-

ment may be more likely to make strategic use of these mastery-avoidance goals than those low in need for achievement. We hypothesized that fear of failure would positively predict performance-approach goals, mastery-avoidance goals, and performance-avoidance goals (Conroy et al., 2003; Elliot & McGregor, 2001; Tanaka, Murakami, Okuno, & Yamauchi, 2002). With regard to the consequences of achievement goal pursuit, we hypothesized that mastery-approach goals would be positive predictors of intrinsic motivation (Harackiewicz, Barron, Tauer, Carter, & Elliot, 2000; Lee, Sheldon, & Turban, 2003; Rawsthorne & Elliot, 1999), whereas mastery-avoidance goals would be negative predictors of intrinsic motivation (Cury, Elliot, Da Fonseca, & Moller, 2006). We hypothesized that performance-approach goals would be positive predictors of performance (Harackiewicz et al., 1997; Urdan, 2004; Wolters, 2004), whereas performance-avoidance goals would be negative predictors of both intrinsic motivation and performance (Elliot & Church, 1997; Finney, Pieper, & Barron, 2004; Pajares & Valiante, 2001).

## Method

### *Participants and Achievement Context*

A total of 229 (76 male, 150 female, and 3 unspecified) undergraduates enrolled in an introductory-level psychology course at a

northeastern university participated in the study in return for extra course credit. Most participants were sophomores or juniors at the university, with a mean age of 19.41 years for the sample. Participants' ethnicity was as follows: 3.93% African American, 16.16% Asian, 68.56% Caucasian, 4.80% Hispanic, 0% Native American, 4.37% other, and 2.18% unspecified. The class was conducted in lecture format, and evaluation was based on a normative grading structure.

### Procedure

The achievement motive and response bias variables were assessed in take-home questionnaire packets during the first 2 weeks of the semester. Participants' achievement goals for their first exam were assessed in a large group session approximately 1 month after the achievement motive and response bias variables were assessed, and 1 week prior to the exam. Intrinsic motivation was assessed in a large group session near the end of the semester, approximately 3 months after the initial take-home assessments. For all assessments, participants were assured that their responses would remain confidential and would in no way influence their course grade. Exam grades were obtained from the professor at the end of the course; participants' SAT scores were obtained from the university registrar.

### Measures

**Need for achievement.** The Achievement Motive subscale of Jackson's (1974) Personality Research Form was used as an indicator of the need for achievement (sample item: "I enjoy difficult work"). A number of empirical investigations have attested to the construct validity of this measure (see Fineman, 1977). Participants responded with *true* (1) or *false* (0) to the 16 items; after reverse scoring eight negatively worded items, the items were summed to form the need for achievement index. Cronbach's  $\alpha$ , computed using the tetrachoric correlation matrix, is .88.

**Fear of failure.** The five-item short form of Conroy's (2001) Performance Failure Appraisal Inventory was used as an indicator of fear of failure (sample item: "When I am failing, I worry about what others think about me"). Several studies have demonstrated the construct validity of this measure (see Conroy & Elliot, 2004). Participants responded on a scale of 1 (*do not believe at all*) to 5 (*believe 100% of the time*), and responses were averaged to form the fear of failure index (Cronbach's  $\alpha = .76$ ).

**Achievement goals.** A series of pilot studies was conducted prior to the present research in the interest of obtaining an optimal set of  $2 \times 2$  achievement goal items. The 12 items listed in Table 1 were eventually selected because they were thought to accurately represent the four goals of the  $2 \times 2$  model while attending carefully to the potential pitfalls reviewed in the introduction. In the present study, the focus of the measure was on students' achievement goals for their first exam in their introductory-level psychology course. Participants responded on a scale of 1 (*strongly disagree*) to 5 (*strongly agree*), and the items were averaged to form the mastery-approach, performance-approach, mastery-avoidance, and performance-avoidance indexes (see Results section for internal consistencies).

**Intrinsic motivation.** Elliot and Church's (1997) eight-item measure was used to assess participants' intrinsic motivation for

the class (sample item: "I think this class is interesting"). The construct validity of this measure has been documented by Elliot and Church (1997). Participants responded on a scale of 1 (*strongly disagree*) to 7 (*strongly agree*); after reverse scoring two negatively worded items, the items were averaged to form the intrinsic motivation index (Cronbach's  $\alpha = .92$ ).

**Response bias.** The 40 items from Paulhus's (1991) Balanced Inventory of Desirable Responding (BIDR) were used to create several different measures of response bias. The BIDR is comprised of two 20-item subscales: Impression Management (IM) and Self-Deceptive Enhancement (SDE). Participants responded to each item using a scale of 1 (*not true*) to 7 (*very true*). Half of the items for each subscale represent desirable statements (e.g., IM: "I always obey laws, even if I'm unlikely to get caught"; SDE: "I always know why I like things"), and half represent undesirable statements (e.g., IM: "When I was young I sometimes stole things"; SDE: "I have not always been honest with myself"). After reverse scoring the undesirable statements, participants received one point for each extreme (6 or 7) response, and their scores for each subscale were summed to form IM and SDE indexes (see Paulhus, 1991, for information on construct validity). An overall BIDR social desirability index was also created by summing the IM and SDE items. Cronbach's  $\alpha$ s for the IM, SDE, and overall BIDR social desirability indexes, computed using the tetrachoric correlation matrices, are .87, .81, and .87, respectively.

Following Elliot and Thrash (2002), we used the BIDR items to also create self-enhancement bias and self-protection bias indexes. Prior to reverse scoring, we summed (across IM and SDE subscales) the number of participants' extreme (6 or 7) responses to the desirable statements and the number of their extreme (1 or 2) responses to the undesirable statements. The first 20-item measure, self-enhancement response bias, represents a tendency to agree with positive statements about oneself that are uncommon, whereas the second 20-item measure, self-protection response bias, represents a tendency to disagree with negative statements about oneself that are common. Cronbach's  $\alpha$ s for these indexes, computed using the tetrachoric correlation matrices, are .78 and .80, respectively.

In addition to the BIDR, the 33-item Marlowe-Crowne Social Desirability Scale (MCSDS; Crowne & Marlowe, 1960) was also used to assess overall social desirability (e.g., "I'm always willing to admit it when I make a mistake"). Participants responded *true* (1) or *false* (0); after reverse scoring 15 negatively worded items, the items were summed to form the MCSDS index. Cronbach's  $\alpha$ , computed using the tetrachoric correlation matrix, is .86.

**Exam performance.** Participants' exam grades were used as a measure of performance attainment. Grades were based on participants' total score on the exam, and each possible grade was assigned a numerical value from 0 to 10 ( $F = 0$ ,  $D = 1$ ,  $D+ = 2$ ,  $C- = 3$ ,  $C = 4$ ,  $C+ = 5$ ,  $B- = 6$ ,  $B = 7$ ,  $B+ = 8$ ,  $A- = 9$ ,  $A = 10$ ). Using total score rather than exam grade as the indicator of performance yielded results essentially identical to those reported in this article.

**SAT scores.** A total SAT score combining the Verbal and Quantitative subscales was used as an index of ability. SAT scores have been shown to predict performance attainment and have been used accordingly as control variables in prior research (Church, Elliot, & Gable, 2001; Elliot & McGregor, 1999).

## Results

*Factorial Structure of Achievement Goals*

Confirmatory factor analyses (CFAs) were conducted on the achievement goal items using AMOS 5.0 (SPSS; Chicago, IL). The analyses were conducted on covariance matrices, and the solutions were generated on the basis of maximum-likelihood estimation. As recommended by Hoyle and Panter (1995), we used several different indexes to evaluate the fit of the models to the data, including chi-square degree of freedom ratio ( $\chi^2/df$ ), comparative fit index (CFI), incremental fit index (IFI), and root-mean-square error of approximation (RMSEA). The following criteria were used to evaluate the adequacy of model fit:  $\chi^2/df \leq 2.0$  (Hair, Anderson, Tatham, & Black, 1995),  $CFI \geq .90$ ,  $IFI \geq .90$ , and  $RMSEA \leq .08$  (Browne & Cudeck, 1993). When multiple models were compared, the Akaike information criterion and Bayesian information criterion were used as well (the lower those values are, the better the fit is).

*Basic CFAs and internal consistencies.* The first CFA examined the hypothesized model, which designated that the items for each goal load on their respective latent factors. To identify the model, the variance of each latent factor was fixed to 1 (Bollen, 1989). The results from this analysis strongly supported the hypothesized model, as not only were all factor loadings quite high (ranging from .93 to .73), but each fit statistic met the criteria for a good fitting model:  $\chi^2(48, N = 229) = 78.32, p < .01, \chi^2/df = 1.63, CFI = .99, IFI = .99, RMSEA = .053$ . All of the subscales demonstrated high levels of internal consistency: For mastery-approach goals, mastery-avoidance goals, performance-approach goals, and performance-avoidance goals, Cronbach's  $\alpha = .84, .88, .92$ , and  $.94$ , respectively.

*Comparison with alternative models.* Additional CFAs investigated the fit of alternative models and compared the fit of the hypothesized and alternative models (see Elliot & McGregor,

2001). Six alternative models were tested: (a) trichotomous model A, in which the performance-approach and performance-avoidance items load on their respective latent factors, and the mastery-approach and mastery-avoidance items load together on a third latent factor; (b) trichotomous model B, in which the mastery-approach and mastery-avoidance items load on their respective latent factors, and the performance-approach and performance-avoidance items load together on a third latent factor; (c) trichotomous model C, in which the mastery-approach and performance-approach items load on their respective latent factors, and the mastery-avoidance and performance-avoidance items load together on a third latent factor; (d) trichotomous model D, in which the mastery-avoidance and performance-avoidance items load on their respective latent factors and the mastery-approach and performance-approach items load together on a third factor; (e) a mastery-performance model in which the mastery-approach and mastery-avoidance items load together on one latent variable, and the performance-approach and performance-avoidance items load together on another; and (f) an approach-avoidance model in which the mastery-approach and performance-approach items load together on one latent variable, and the mastery-avoidance and performance-avoidance items load together on another.

As may be seen in Table 2, the fit indexes indicate that none of the alternative models provided a good fit to the data, and log-likelihood ratio tests show that the hypothesized model provided a far better fit than any of the alternative models. It is worth noting that although the Pearson product moment correlations between some pairs of goal subscales were rather high (i.e., mastery-approach and mastery-avoidance,  $r = .51$ ; mastery-avoidance and performance-avoidance,  $r = .46$ ; performance-approach and performance-avoidance,  $r = .68$ ), our data clearly show that the goals within these pairings are not equivalent.

*CFAs controlling for response bias.* To examine response bias, we created five data sets from the original data set by

Table 2  
*Comparison With the 2 × 2 Model and Alternative Models*

Variable	Overall fit indices					
	$\chi^2/df$	CFI	IFI	RMSEA	AIC	BIC
Hypothesized model	1.63	.99	.99	.053	138.3	241.3
Trichotomous Model A	5.81	.89	.89	.145	350.2	442.9

residualizing various forms of response bias out of each achievement goal item. These new data sets are: (a) an approach-avoidance residualization data set, in which self-enhancement bias scores were residualized out of each mastery-approach and performance-approach item, whereas self-protection bias scores were residualized out of each mastery-avoidance and performance-avoidance item; (b) an SDE residualization data set, in which SDE scores were residualized out of each achievement goal item; (c) an IM residualization data set, in which IM scores were residualized out of each achievement goal item; (d) an overall BIDR residualization data set, in which overall BIDR scores were residualized out of each achievement goal item; and (e) an MCSDS residualization data set, in which MCSDS scores were residualized out of each achievement goal item.

CFAs using each of these data sets indicated that the data were a good fit to the model (Table 3); all factor loadings were highly significant and nearly identical with those from the original data set. These results suggest that the four-factor structure of achievement goals is not an artifact of response bias.

To address the response bias issue more extensively, we examined whether achievement goals and response bias form a common factor (Beretvas, Meyers, & Leite, 2002). First, we constructed a CFA model with five factors: four achievement goal factors and one response bias factor. The achievement goal piece of the model was identical to the CFA model reported above. The response bias factor represented one of six types of response bias (SDE, IM, self-enhancing response bias, self-protecting response bias, overall BIDR, or MCSDS). When the response bias factor reflected SDE, IM, self-enhancement response bias, or self-protection response bias, the response bias latent factor was comprised of two 10-item parcels, randomly selected from their corresponding measures. When response bias reflected overall BIDR, two randomly selected 20-item parcels were used as indicators of the latent factor; and when response bias reflected MCSDS, two randomly selected 16-item and 17-item parcels were used as indicators of the latent factor. These five-factor models were compared with their corresponding four-factor models, created by collapsing one achievement goal factor and the response bias factor into a single factor. With four achievement goals and six response bias indicators, a total of 24 model comparisons were conducted using the log-likelihood ratio test. In each comparison, the five-factor model was found to fit significantly better than the four-factor model,  $\chi^2_{diff}(4,$

$N = 221) \geq 54.61, ps < .001$ , indicating that each of the achievement goal variables is clearly distinct from response bias.

*Investigation of the effect of prefix similarity.* As stated earlier, our achievement goal measure uses three prefixes for each achievement goal, and these prefixes are the same across the four goals. As such, it is possible to control for extraneous phrasing effects, which may afford a more precise assessment of each achievement goal construct. On the other hand, it is possible that items using the same phrase have substantial correlated errors, which would distort our results.

To address this issue, we examined whether assuming a correlation between error variables using the same prefix would improve model fit. Eighteen error correlations (for each prefix, six pairs of items can be made) were investigated one by one with log-likelihood ratio tests. The critical ratio was set to .01 to prevent the inflation of Type I error. The results indicated that none of the 18 correlations between error variables significantly improved the fit of the model. Moreover, in all models, each factor loading remained highly significant and was nearly identical to that with the original model. Therefore, it is clear that our results are not contaminated by systematic error attributable to the common wording of the items.

In sum, the results reported above provide strong support for the four-factor model of achievement goals. Alternative factor models could not explain the data better than the four-factor model. Neither response bias nor prefix similarity distorted the results. Given the good fit of the four-factor model and the high internal consistency of the achievement goal subscales, participants' responses on the items for each hypothesized factor were averaged to form the four achievement goal indexes. Table 4 reports the descriptive statistics of the main variables in this study.

### *The Dimensional Structure of Achievement Goals*

*The multiple-indicator correlated trait-correlated method (MI CT-CM) model.* Although the preceding analyses showed that the four-factor model is highly robust, they do not address the  $2 \times 2$  structure of achievement goals per se. That is, from a theoretical perspective, the valence of competence (positive for approach or negative for avoidance) should be crossed with the definition of competence (mastery or performance), resulting in four separate factors. CFA alone is silent with regard to this dimensional structure. To test the two-dimensional nature of achievement goals, we applied an MI CT-CM model (Marsh & Hocevar, 1988; see also Eid, Lischetzke, Nussbeck, & Trierweiler, 2003) to the data.

An MI CT-CM model is a model typically applied to the multitrait multimethod (MTMM) matrix (Campbell & Fiske, 1959) and is a simple extension of a CT-CM model (Jöreskog, 1974; Marsh & Grayson, 1995). Although our data are not in MTMM format, this model provides us with a way to confirm the dimensionality of the hypothesized constructs. In this model (Figure 1), which can be regarded as akin to a second-order factor analysis model, both the valence and definition dimensions of competence are expected to have additive effects on an achievement goal factor. The valence dimension consists of an approach factor and an avoidance factor, only one of which is applicable to any given goal factor; likewise, the definition dimension consists of a mastery factor and a performance factor, only one of which is applicable to any given goal factor. For example, the mastery-

Table 3  
*Fit Indices for the  $2 \times 2$  Model After Residualizing Response Bias*

Data set	$\chi^2/df$	CFI	IFI	RMSEA
Original data set	1.63	.99	.99	.053
App-av residualization data set	1.66	.99	.99	.055
SDE residualization data set	1.68	.99	.99	.054
IM residualization data set	1.65	.99	.99	.054
Overall BIDR residualization data set	1.65	.98	.98	.056
Overall MCSDS residualization data set	1.70	.98	.98	.056

*Note.* CFI = comparative fit index; IFI = incremental fit index; RMSEA = root-mean-square error of approximation; app-av = approach-avoidance; SDE = self-deceptive enhancement; IM = impression management; BIDR = Paulhus's (1991) Balanced Inventory of Desirable Responding; MCSDS = Marlowe-Crowne Social Desirability Scale.

approach factor is posited to be explained by both the mastery factor and the approach factor. Although factors within each dimension can correlate with each other, it is assumed that factors across dimensions (e.g., the approach factor and the performance factor) are uncorrelated. Thus, the valence and definition dimensions each contribute independently to the achievement goal factors, which allows the achievement goal factor to be decomposed into valence, definition, and unique residual components. This type of model is sometimes called an *additive model*, because each component additively contributes to the construct.

The model was fit to the data using maximum likelihood estimation (Figure 1). To identify the model, we constrained paths from the same second factors to be equal and fixed the covariance between the mastery and performance factors to 0.<sup>2</sup> The model provided a good fit to the data:  $\chi^2(49, N = 229) = 78.54, p < .01$ ,  $\chi^2/df = 1.60$ , CFI = .99, IFI = .99, RMSEA = .051, and all path coefficients were significant. These results nicely support the  $2 \times 2$  dimensionality of the four achievement goals.

*Other alternative models.* Although the MI CT-CM model provided a good fit to the data, other types of models may be examined with regard to the precise structure of achievement goals. Here we describe some plausible alternative models and compare them with the MI CT-CM model.

The first alternative model is a form of two-level model, an example of which is depicted in Figure 2. In this model, the four achievement goal factors themselves make up a two-factor structure. There are two possible types of two-level structures: (a) a mastery–performance two-level model, in which a mastery factor (consisting of mastery-approach and mastery-avoidance factors) and a performance factor (consisting of performance-approach and performance-avoidance factors) are formed as second-order factors; and (b) an approach–avoidance two-level model, in which an approach factor (consisting of mastery-approach and performance-approach factors) and an avoidance factor (consisting of mastery-avoidance and performance-avoidance factors) are formed as second-order factors. The critical difference between the MI CT-CM model and these two-level models is that the two-level models derive factors out of only one dimension of the  $2 \times 2$  model.

We constrained paths from the same second factors to be equal because freeing those parameter estimates makes the solution very unstable (i.e., showing an improper solution and abnormally high standardized factor loadings). Fitting these models to the data, we obtained a worse fit than the MI CT-CM model (Table 5). More-

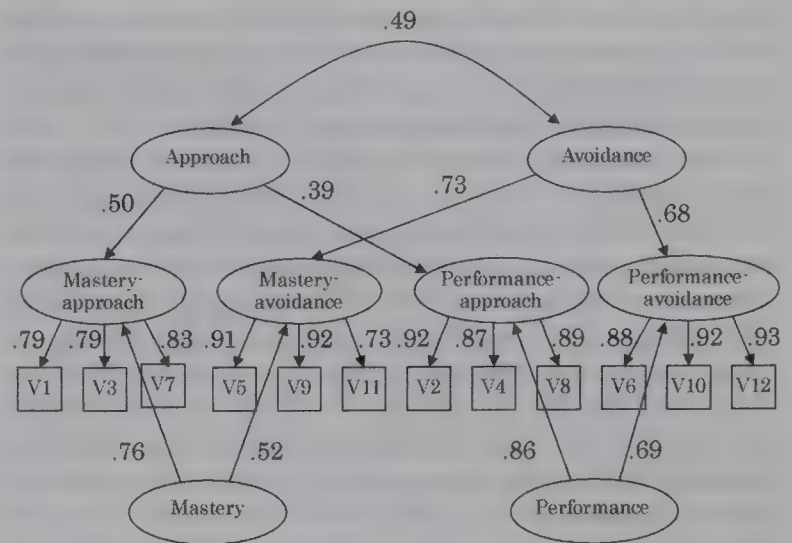

Figure 1. MI CT-CM model of achievement goals. Estimates are standardized. All coefficients are significant ( $p < .01$ ). Error variables are not represented in order to simplify the presentation. V1–V12 represent the individual items of the scale (numbers indicate the order of items in the questionnaire; see Table 1).

over, in the approach–avoidance two-level model, the correlation between the approach and avoidance factors exceeded 1.0.

The second alternative model is a direct product model (Browne, 1989; Wothke & Browne, 1990), which is also typically applied to an MTMM matrix. Whereas a CT-CM model assumes additive (independent) effects of two dimensions, the direct product model assumes only multiplicative effects. That is, the effect of one dimension is posited to completely be a function of the other dimension. For example, the effect of approach factor on mastery-approach factor is assumed to change depending on the strength of the mastery factor. This model is sometimes called a *multiplicative model*, and is compared with an additive model (for further discussion on these two types of model, see Goffin & Jackson, 1992; Hernandez & Gonzalez-Roma, 2002). When there are  $m \times n$  variables comprising the  $m \times n$  dimensional structure, the direct product model expresses the covariance matrix as

$$\Sigma = \mathbf{D}(\Sigma_{D1} \otimes \Sigma_{D2} + \Delta)\mathbf{D},$$

where  $\Sigma_{D1}$  is a  $(m \times m)$  latent variable score correlation matrix of Dimension 1, and  $\Sigma_{D2}$  is a  $(n \times n)$  latent variable score correlation matrix of Dimension 2.  $\mathbf{D}$  is a  $(mn \times mn)$  positive definite diagonal matrix of scale constants.  $\Delta$  is a  $(mn \times mn)$  diagonal matrix of nonnegative unique error components. We set  $m = n = 2$  and applied this covariance structure to the factor correlations of our CFA model. Accordingly, the covariance matrix of our 12 items can be expressed as

$$\Sigma_v = \mathbf{A}\mathbf{D}(\Sigma_{D1} \otimes \Sigma_{D2} + \Delta)\mathbf{D}\mathbf{A}' + \Sigma_E,$$

where  $\mathbf{A}$  is a  $(12 \times 4)$  matrix of factor loadings in the CFA, and  $\Sigma_E$  is a  $(12 \times 12)$  nonnegative diagonal matrix of error variances for the CFA. In our analysis,  $\mathbf{D}$  was set as an identity matrix to identify the model. Maximum likelihood estimates were obtained

<sup>2</sup> This restriction is reasonable because much empirical research has revealed that mastery and performance goals are independent of each other.

Table 4  
Descriptive Statistics

Variable	<i>M</i>	<i>SD</i>	Observed range	Possible range
Need for achievement	9.63	3.47	1.00–16.00	0.00–16.00
Fear of failure	2.99	0.89	1.00–5.00	1.00–5.00
Mastery-approach goals	4.23	0.67	1.67–5.00	1.00–5.00
Mastery-avoidance goals	3.61	0.95	1.00–5.00	1.00–5.00
Performance-approach goals	4.05	0.94	1.00–5.00	1.00–5.00
Performance-avoidance goals	3.83	1.06	1.00–5.00	1.00–5.00
Intrinsic motivation	5.59	1.09	1.00–7.00	1.00–7.00
Exam performance	6.37	2.00	1.00–10.00	0.00–10.00

using Mx (Neale, Boker, Xie, & Maes, 1999). As may be seen in Table 5, this model evidenced a worse fit to the data than the MI CT-CM model; furthermore, three variance components were negative (i.e., the model yielded an improper solution).

In sum, two types of alternative models (a two-level model and a direct product model) were compared with our proposed MI CT-CM model to further explore the nature of the structure of achievement goals. The results were clear: Neither of these alternative models was superior to the MI CT-CM model, both in terms of fit indexes and acceptability of solutions. In other words, our results indicate that achievement goals are comprised of two independent dimensions. Focusing on one of the dimensions (a two-level model) or on the multiplicative effects of the dimensions (a direct product model) cannot precisely capture the structure of achievement goals.

Testing the Hierarchical Model

We used structural equation modeling (SEM) to test the hierarchical model of approach-avoidance achievement motivation, in which achievement goals are posited to represent intermediate variables between motive dispositions and outcome variables such as performance attainment and intrinsic motivation (Elliot, 2006; Elliot & Church, 1997). We began by establishing the measurement portion of our model within a CFA framework (cf. Anderson and Gerbing, 1988) and then proceeded to the full SEM model.

*Measurement model.* The measurement model consisted of the need for achievement, fear of failure, the four achievement goals, intrinsic motivation, and exam performance. Fear of failure and each achievement goal latent variable were represented by the individual items from their respective scales. The need for achievement latent variable was represented by four parcels randomly selected from the 16 items of the scale. Likewise, the intrinsic motivation latent variable was represented by four parcels randomly selected from the 8 items of the scale. Exam performance was an observed variable; SAT scores were residualized out of the exam performance variable to control for the influence of ability.<sup>3</sup> In this model, the loadings between the indicators and the latent factors were freely estimated, and all exogenous variables were free to correlate with each other. The model was a good fit to the data:  $\chi^2(272, N = 229) = 442.16, p < .01, \chi^2/df = 1.62, CFI =$

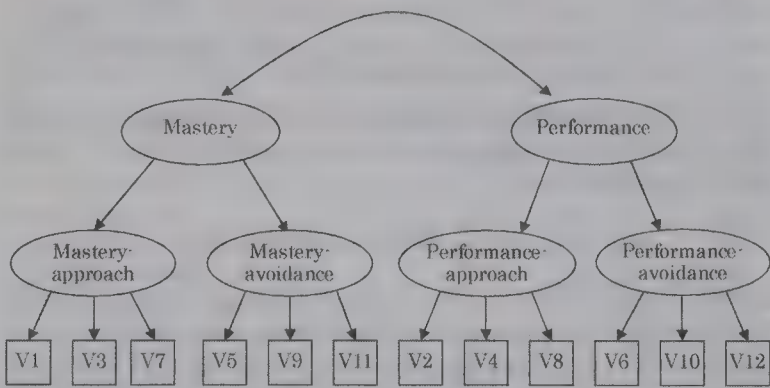

Figure 2. An example of a two-level model of achievement goals. Error variables are not represented in order to simplify the presentation. V1–V12 represent the individual items of the scale (numbers indicate the order of items in the questionnaire; see Table 1).

Table 5  
Fit Indices of CT-CM Model and Other Alternative Models

Model	$\chi^2/df$	CFI	IFI	RMSEA	AIC	BIC
MI CT-CM model	1.60	.99	.99	.051	136.5	236.1
Mastery–performance two-level model	3.18	.95	.95	.098	216.2	308.9
Approach–avoidance two-level model	4.60	.91	.91	.126	290.4	383.1
Direct product model	3.06	—	—	.095	211.2	300.4

Note. CFI = comparative fit index; IFI = incremental fit index; RMSEA = root-mean-square error of approximation; AIC = Akaike information criterion; BIC = Bayesian information criterion; MI CT-CM = multiple-indicator correlated trait–correlated method. Dashes indicate that data were not obtained.

.95, IFI = .95, RMSEA = .052, and all factor loadings were highly significant ( $p < .001$ ).

*Full SEM model.* In the full SEM model, we posited that the achievement motives would lead to achievement goals that, in turn, would directly predict the outcome variables. Specifically, the need for achievement was hypothesized to positively predict mastery-approach goals, performance-approach goals, and, tentatively, mastery-avoidance goals; fear of failure was hypothesized to positively predict mastery-avoidance goals, performance-avoidance goals, and performance-approach goals. Mastery-approach goals were hypothesized to be positive predictors of intrinsic motivation, whereas mastery-avoidance goals were posited to be negative predictors of intrinsic motivation. Performance-approach goals were hypothesized to be positive predictors of exam performance, whereas performance-avoidance goals were posited to be negative predictors of both intrinsic motivation and exam performance. Given the similar wording of the performance-approach and performance-avoidance goal items and the mastery-approach and mastery-avoidance goal items, we allowed for correlated errors between these two latent variables (Elliot & Church, 1997).

In an initial test of the model, all hypothesized paths were significant with the single exception of that between mastery-avoidance goals and intrinsic motivation. The model was thus tested in the final analysis with this path removed. The model provided a good fit to the data:  $\chi^2(288, N = 229) = 550.73, p < .01, \chi^2/df = 1.91, CFI = .92, IFI = .92, RMSEA = .063$ , and all factor loadings were highly significant ( $p < .001$ ). Regarding the antecedents of achievement goals, the need for achievement was a positive predictor of mastery-approach goals ( $\beta = .34, p < .01$ ), performance-approach goals ( $\beta = .22, p < .01$ ), and mastery-avoidance goals ( $\beta = .21, p < .01$ ), whereas fear of failure was a positive predictor of performance-avoidance goals ( $\beta = .31, p < .01$ ), mastery-avoidance goals ( $\beta = .15, p < .05$ ), and performance-approach goals ( $\beta = .24, p < .01$ ). Regarding the consequences of achievement goals, mastery-approach goals were a positive predictor of intrinsic motivation ( $\beta = .28, p < .01$ ), performance-approach goals were a positive predictor of exam

<sup>3</sup> Given that there are some missing values for the SAT scores, the full information maximum likelihood method was used to avoid loss of information due to the missing data (Arbuckle, 1996; Schafer & Graham, 2002).

performance ( $\beta = .46, p < .01$ ), and performance-avoidance goals were a negative predictor of both intrinsic motivation ( $\beta = -.15, p < .05$ ) and exam performance ( $\beta = -.48, p < .01$ ). See Figure 3 for a pictorial summary of these findings.

In sum, SEM analyses yielded data that strongly supported the hierarchical model of approach-avoidance achievement motivation. Both the measurement model and the full SEM model provided a good fit to the data, and the path results in the full SEM model were nearly perfectly consistent with predictions.

### *Comparing the Present Data and the Elliot and McGregor (2001) Data*

Finally, we thought it would be informative to compare the data from the present study with that from the original research with the AGQ (see Elliot & McGregor, 2001). First, we considered the achievement goal reliabilities and the intercorrelations among the achievement goal variables (see Table 6). The internal consistencies for all four goals were strong (greater than .80) in both the present research and the Elliot and McGregor (2001) research. The one noticeable difference was that the  $\alpha$  for performance-avoidance goals was .83 with the AGQ, whereas the  $\alpha$  was .94 for performance-avoidance goals with the AGQ-R. This enhanced reliability is likely due to the explicit normative focus included in all three performance-avoidance goal items in the AGQ-R. The achievement goal intercorrelations were the same in the present research and in the Elliot and McGregor (2001) research, except that mastery-approach and performance-approach goals were significantly positively correlated in the AGQ-R, whereas in the AGQ they were not. This positive correlation is in line with predictions because these two goals share a competence dimension (both are approach goals).

Second, we considered achievement motives as simultaneous predictors of achievement goal adoption (see Table 7). The pre-

dictive patterns were the same in the present research and in the Elliot and McGregor (2001) research, with one exception: Need for achievement was a significant positive predictor of AGQ-R mastery-avoidance goals, but not AGQ mastery-avoidance goals. This positive relation is in line with our predictions regarding mastery-avoidance goals as strategic tools that are sometimes put to effective use by highly achievement-oriented individuals.

Third, we considered the achievement goals as simultaneous predictors of exam performance (see Table 8; intrinsic motivation was not examined in the Elliot & McGregor [2001] research). The predictive patterns were the same in the present research and in the Elliot and McGregor (2001) research.

In sum, comparison of the present data and the Elliot and McGregor (2001) data highlights the value of the AGQ-R measure. This new measure yielded results that replicated all of the important findings from the original research; when the results from the present and prior research diverged, it was the present results that were more in line with our theoretical model. Thus, the AGQ-R appears to illustrate that it is indeed possible to address the measurement problems highlighted at the beginning of this article without sacrificing structural validity and predictive utility.

### Discussion

Sustained progress within a psychological literature requires clear operationalization of the focal constructs in the literature that is consistent with the way that the constructs are conceptualized. In the present research, we have identified several problems with existing measures in the achievement goal literature; some of them seem relatively minor (e.g., some performance-based goal items focus on extreme groups), but others seem to be of considerable importance (e.g., some achievement goal items may not actually focus on goals per se). These problems tend to go unnoticed by researchers or, when noticed, tend to simply be acknowledged in

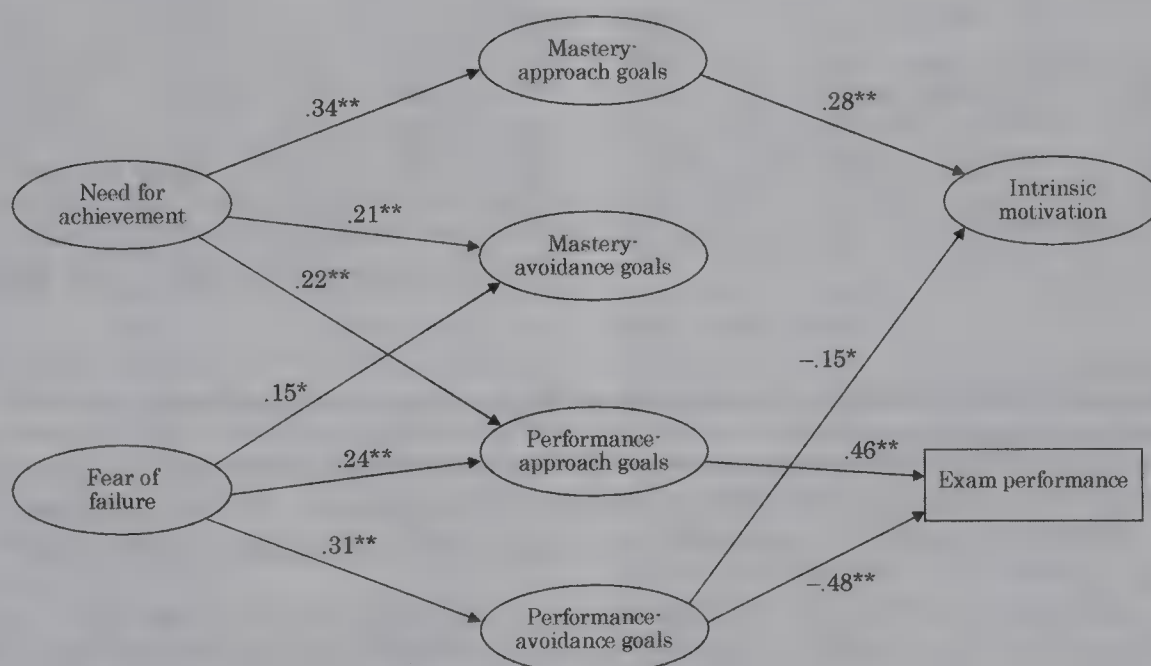

Figure 3. Hierarchical model of achievement goals. Estimates are standardized. Indicator variables, error variables, and correlations between error variables are not represented in order to simplify the presentation. \* $p < .05$ . \*\* $p < .01$ .

the discussion section of empirical articles or noted as an issue to attend to in future research. Our work herein was designed to make these problems salient and to illustrate them by critiquing a commonly used achievement goal measure—the AGQ (Elliot & McGregor, 2001). In addition, our work was designed to attend to these problems in a direct and concrete way by revising the AGQ accordingly. The resulting measure—the AGQ-R—was then put to the test to examine both its structural validity and its predictive utility.

With regard to structural validity, the measure fared extremely well when subjected to a highly rigorous set of analyses. The hypothesized four-factor structure of the achievement goal items was confirmed, and this four-factor structure was found to be a better fit to the data than a series of alternative models with three- and two-factor structures. Additional analyses demonstrated that the four-factor structure was not a mere artifact of self-enhancement, self-protection, self-deception, impression management, or general social desirability. Each of the four achievement goal factors had a high degree of internal consistency. We not only confirmed the four-factor structure in our analyses but also confirmed the two-dimensional structure posited by the 2 (definition) × 2 (valence) achievement goal model. This two-dimensional model also was shown to fit the data better than two types of alternative models.

With regard to predictive utility, results from SEM analyses were strongly supportive. The measurement model was a good fit to the data, as was the path model in which achievement motives were posited as predictors of achievement goals and the goals, in turn, were posited as direct predictors of achievement-relevant outcomes. Mastery-approach and performance-avoidance goals were shown to emerge from a single antecedent, the need for achievement and fear of failure, respectively, whereas performance-approach and mastery-avoidance goals were shown to emerge from both of these achievement motives. Mastery-approach goals were positive predictors and performance-avoidance goals were negative predictors of intrinsic motivation; performance-approach goals were positive predictors and performance-avoidance goals were negative predictors of exam performance. These results were nearly perfectly in accord with our hypotheses; the only hypothesized relation that was not supported was that between mastery-avoidance goals and intrinsic motivation (to be discussed in more detail below). In short, analyses focused on both structural validity and predictive utility yielded strong support for the AGQ-R; the measure appears to be empirically as well as conceptually sound. In addition, comparison of the AGQ-R data from the present research with the AGQ data from prior research casts the AGQ-R in a very positive light.

An important feature of the present research was our examination of the dimensional as well as factorial structure of achievement goals. Our dimensional findings are noteworthy because they are the first empirical evidence indicating that each of the four goals of the 2 × 2 model indeed represents a combination of two underlying competence dimensions. Thus, although each of the

goals is a unique combination of dimensions and therefore is distinct, some goals share a dimension and therefore are conceptually related, whereas others do not share a dimension and therefore are conceptually unrelated. The two goals that are composed of completely different dimensions—mastery-approach and performance-avoidance goals—exhibited starkly different empirical profiles in our research. This is true with regard to both antecedents (they emerged from completely different achievement motives) and consequences (they had completely different effects on intrinsic motivation and exam performance).

It is interesting that even among achievement goals that share a dimension there is variability in the strength of relation between them. For example, in our research, performance-approach and performance-avoidance goals were strongly correlated ( $r = .68$ ), whereas mastery-approach and performance-approach goals were not ( $r = .16$ ). One observation on the observed pattern of correlations is that goals sharing a common definition dimension appear to be more closely related than goals sharing a common valence dimension. Another observation is that the strongest link between any two goals appears to be that between performance-approach and performance-avoidance goals. This link is of particular interest because it has led some to question whether these two forms of regulation can truly be separated at the phenomenological level (Roeser, 2004; Urdan & Mestas, 2006) and has led others to fear that performance-approach goals quickly transform into performance-avoidance goals once failure or difficulty is encountered (Brophy, 2005; Midgley et al., 2001). It is possible, however, that the adoption of performance-approach goals evokes perceptual-cognitive processes that are not only functionally and experientially separate from avoidance concerns (Cacioppo, Gardner, & Berntson, 1997; Elliot, 2006) but also bias information processing toward information and interpretation that sustains an approach form of regulation, even in the face of failure (Elliot & Harackiewicz, 1996; Kunda, 1990). Research is clearly needed to directly address this important issue. In addition, a fascinating avenue for research would be to explore moderators of the relation between performance-approach and performance-avoidance goal adoption. We suspect that the joint adoption of these goals is most prevalent in highly evaluative achievement environments and among people with high fear of failure or low competence perceptions.

Mastery-avoidance goals are the most recent addition to the achievement goal literature and are the least researched and least understood of the four goals in the  $2 \times 2$  model. Our antecedent results shed some light on the nature of these goals, as they were found to emerge from both the need for achievement and fear of failure. Prior research has linked mastery-avoidance goals to fear of failure alone (Conroy & Elliot, 2004; Elliot & McGregor, 2001); it took a cleansing of negative affect from the original mastery-avoidance items for the conceptually sensible link between the need for achievement and these mastery-based goals to appear. This, of course, nicely illustrates the empirical value of attending to the conceptual problems plaguing the AGQ and other existing achievement goal measures.

Although clarity was obtained regarding the antecedents of mastery-avoidance goals, clarity remained elusive regarding the consequences of these goals, as they were not negative predictors of intrinsic motivation as anticipated (see Cury et al., 2006). As a combination of the most positive component of achievement goals (mastery) and the most negative (avoidance), mastery-avoidance

goals represent a puzzling motivational hybrid, and it simply is not clear how these two seemingly discordant components operate together in the process of goal regulation. Perhaps in some achievement contexts or for some persons the mastery component of the goal predominates, leading to relatively positive consequences, whereas in other contexts or for other persons the avoidance component predominates, leading to relatively negative consequences. And perhaps most often, the positive and negative components of the goal cancel each other out, leading to neither positive nor negative consequences (as found in the present work). The conceptual and empirical complexities inherent in mastery-avoidance goals can be frustrating at this early stage of study, and it appears that the adoption and pursuit of a mastery-approach goal (with accompanying persistence and task absorption) will be needed for researchers exploring this currently opaque form of regulation.

Although the revised mastery-avoidance goal scale yielded results different from those obtained with the original scale, it is important to note that the revised scales for the other three goals yielded results fully in accord with those from the original scales (and other measures focused on these goals as well). This is reassuring on two fronts. First, and most specifically, it highlights the utility of achievement goals per se as predictors of important achievement-relevant outcomes. Second, and more generally, it indicates that the problems identified herein with existing measures are not so severe as to produce a completely spurious empirical corpus. Indeed, it is difficult to imagine the achievement goal approach rising to its lofty status in the field unless the existing measures captured, to a great extent, systematic and conceptually relevant variance. However, we do think that the problems that we have identified muddy the waters by adding unsystematic and conceptually irrelevant variance to the assessment process and that this muddying of the waters has kept the achievement goal approach from developing to its full potential. It is our hope that additional clarity and precision on the measurement front will translate into additional clarity and precision on the empirical front and will help the achievement goal literature move forward.

We view our revised achievement goal measure as an improvement on the AGQ, but we in no way view the AGQ-R as some sort of final or definitive assessment tool. On the contrary, in the achievement goal literature and in psychological literatures more generally, we view measurement development as part and parcel of theory development, such that with advances or refinements in theory comes the need for revised or new measures. For example, Elliot (1999) stated that mastery-based goals may be differentiated in terms of whether a task-based or intrapersonal standard is used in competence evaluation. The AGQ-R is somewhat ambiguous on this issue, although the most straightforward reading of the items suggests a task-based focus (see Van Yperen, 2006, for mastery-based goals that use an intrapersonal focus). Embracing this  $3 \times 2$  achievement goal framework will necessitate the development of a new measure that explicitly differentiates task-based mastery goals from intrapersonal mastery goals. We think the time has come to move in this direction, as we think it highly likely that each of the six goals in the  $3 \times 2$  model will indeed demonstrate factorial separability and discriminant predictive utility.

It should also be highlighted that there is room for disagreement as to how achievement goals should be conceptualized, particu-

larly with regard to the performance-mastery distinction, and this clearly has implications for achievement goal measurement. One ongoing issue is whether performance-based goal measures should include a demonstration component as well as a normative component (Elliot, 2006; Urdan & Mestas, 2006). The AGQ-R focuses exclusively on the normative component, leaving the demonstration component as an optional feature that may appear in performance-based goal complexes (see Elliot & Thrash, 2001) but need not be present in all performance-based goal pursuit. Another ongoing issue, albeit one that has received less attention, is whether the focal point of performance and mastery goals should be the same or different. The AGQ-R follows convention in having performance-based goals focus on performing and having mastery-based goals focus on learning (see Dweck, 1986), but it would be possible (although, we suspect, not desirable for most) to devise items that eliminated this distinction altogether. Finally, we should acknowledge that our research focused on college undergraduates in a classroom context; the generalizability of our results to other ages and contexts remains an open question.

One reason for explicating the measurement problems present in the achievement goal literature is to highlight the need for improved measures, the use of which, it is hoped, will improve the quality of the empirical literature and the effectiveness of applied endeavors. However, we close by noting another, broader reason for striving for improved achievement goal assessment. Achievement goals are but one of the many constructs necessary to fully account for behavior in achievement settings. Other constructs such as motives, values, emotions, and competence perceptions, to name a few, are also important to include in models of achievement motivation (for a review of constructs, see Anderman & Wolters, 2006; Elliot & Dweck, 2005). Existing measures of achievement goals often include content that more readily belongs in measures of these other constructs. As the achievement goal literature matures it will undoubtedly move more and more in the direction of linking goals to these other constructs in integrative fashion. A conceptually clean achievement goal measure would seem a prerequisite for this integration process to transpire smoothly.

# The Relationships Among Students' Future-Oriented Goals and Subgoals, Perceived Task Instrumentality, and Task-Oriented Self-Regulation Strategies in an Academic Environment

Sharon E. Tabachnick  
University of Memphis

Raymond B. Miller  
University of Oklahoma, Norman

George E. Relyea  
University of Memphis

The authors performed path analysis, followed by a bootstrap procedure, to test the predictions of a model explaining the relationships among students' distal future goals (both extrinsic and intrinsic), their adoption of a middle-range subgoal, their perceptions of task instrumentality, and their proximal task-oriented self-regulation strategies. The model was based on R. B. Miller and S. J. Brickman's (2004) conceptualization of future-oriented motivation and self-regulation, which draws primarily from social-cognitive and self-determination theories. Participants were 421 college students who completed a questionnaire that included scales measuring the 5 variables of interest. Data supported the model, suggesting that students' distal future goals (intrinsic future goals in particular) may be related to their middle-range college graduation subgoal, to their perceptions of task instrumentality, and to their adoption of proximal task-oriented self-regulation strategies.

**Keywords:** future and proximal goals, perceived task instrumentality, social-cognitive theory, self-determination theory, intrinsic and extrinsic goals

Miller and Brickman (2004) proposed a model of future-oriented motivation and self-regulation that had the expressed purpose of integrating future and proximal motivation and self-regulation variables. This model drew heavily from social-cognitive theory (Bandura, 1997), self-determination theory (Deci & Ryan, 2000; Ryan & Deci, 2000), personal investment theory (Maehr, 1984), future-time perspective theory (Nuttin, 1985), and the future-oriented extension of achievement motivation theory (Raynor, 1974; Raynor & Entin, 1982). Miller and Brickman's (2004) model, depicted in Figure 1, consists of two major interconnected parts, *future-oriented regulation* and *proximal self-regulation processes*. The full model has been described in detail elsewhere (Miller & Brickman, 2004; Tabachnick, 2005). The backbone of the model is delineated by four major variables (see circled variables in Figure 1) that clearly connect future goals with proximal subgoals, with perceived task instrumentality, and finally, with proximal task-oriented self-regulation. The purpose of the present study was to test a specific portion of Miller and Brickman's (2004) model

to examine the relationships among the four major variables explaining the connection between the hypothesized future and proximal motivation and self-regulation processes. The four variables of interest in the present study were future goals, proximal subgoals, perceived task instrumentality, and task-oriented self-regulation strategies (see Figure 1).

Miller and Brickman (2004) contended that students' distal future goals (e.g., personal growth, contribution to community, personal relationships, etc.) influence the adoption of proximal subgoals in the service of the future goals; that the proximal subgoals lead to perceptions of task instrumentality on the part of students exposed to learning tasks; and that perceived task instrumentality, in turn, leads to proximal task-oriented self-regulation. Although Miller and Brickman (2004) defined personally valued future goals in terms of Deci and Ryan's (2000; also Ryan & Deci, 2000) self-determined future aspirations, they stopped short of differentially modeling future goals in an extrinsic versus intrinsic manner, as Kasser and Ryan (1993, 1996) did.

However, the picture that is beginning to emerge from recent research is that aspiring to attain intrinsic and extrinsic future goals has an important impact on well-being, the quality of task engagement, and achievement. For example, Kasser and Ryan (1993, 1996) have found that aspirations for money and wealth (considered "extrinsic" by self-determination theory) are associated with decreased well-being and mental health in comparison with aspirations for benefitting community and personal growth (considered

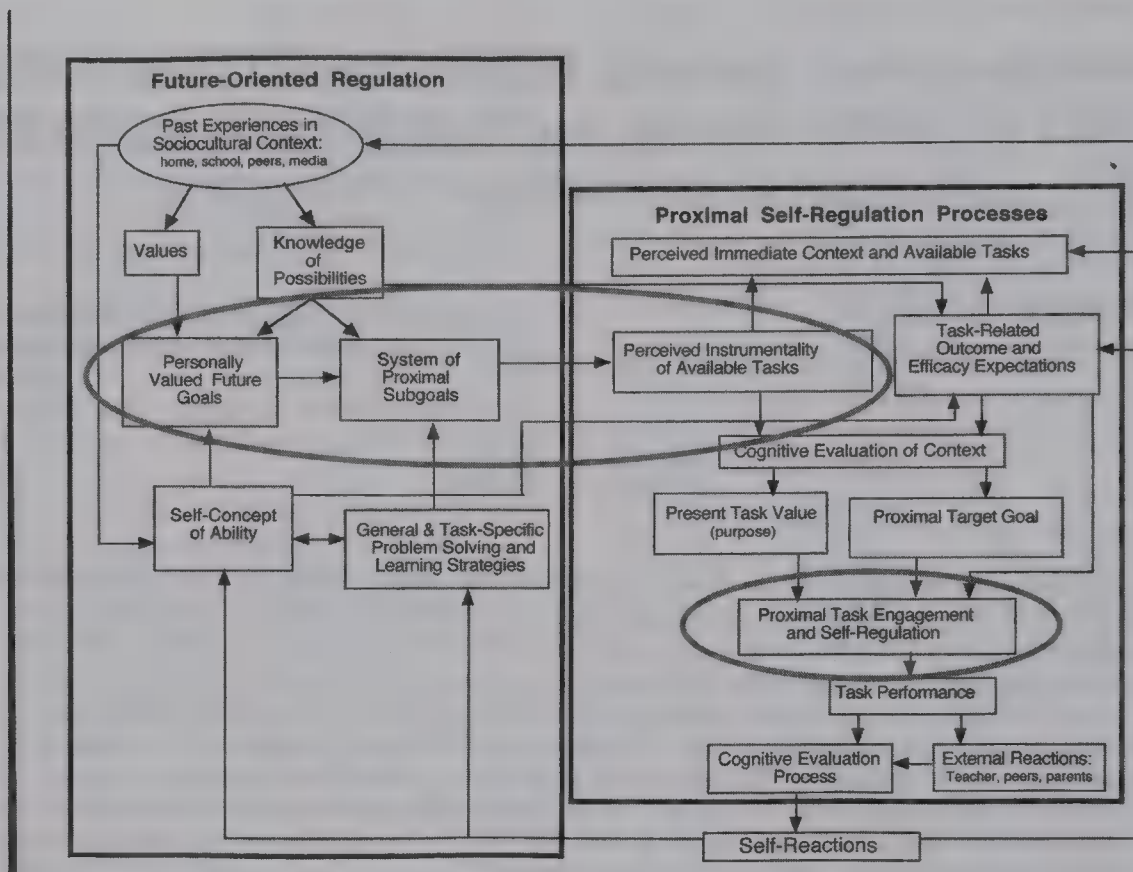

Figure 1. Model of future-oriented motivation and self-regulation, with the variables of interest to the present study circled. From "A model of future-oriented motivation and self-regulation," by R. B. Miller and S. J. Brickman, 2004, *Educational Psychology Review*, 16, p. 13, Figure 1. Copyright 2004 by Springer/Kluwer Academic Publishers. Reproduced and adapted with kind permission of Springer Science and Business Media.

"intrinsic" by self-determination theory).<sup>1</sup> Simons, Dewitte, and Lens (2000, 2004) found, among other things, that students performing tasks because of intrinsic future consequences (e.g., personal growth) were significantly more likely to adopt task or mastery goals and, in addition, had more interest and confidence in their studies, persisted longer, used more deep learning strategies, and received better exam scores than students who performed tasks because of extrinsic future consequences (e.g., high earnings). In a series of studies about experimentally induced goals, Vansteenkiste, Simons, Lens, Sheldon, and Deci (2004) and Vansteenkiste, Simons, Soenens, and Lens (2004) similarly found that framing tasks in terms of intrinsic future goals (e.g., the task is important for personal growth or health in the future) resulted in better test performance, a significantly larger amount of deep processing and a smaller amount of shallow processing, and higher persistence than did framing tasks in terms of extrinsic future goals (e.g., the task is important for money or an attractive image in the future).

Finally, in a comprehensive review of the intrinsic-extrinsic future goal content literature relating specifically to academic outcomes, Vansteenkiste, Lens, and Deci (2006) commented that despite the fact that "only very recently have these differential [intrinsic-extrinsic future] goal contents been linked to academically relevant outcomes" (p. 23), evidence increasingly points in the direction indicating that intrinsic future goal content may be related to adaptive academic outcomes, whereas extrinsic future goal content may be related to maladaptive academic outcomes. Based on the research in this area, we decided to include a

distinction between intrinsic and extrinsic future goals in our test of predictions from the Miller and Brickman (2004) model.

Miller and Brickman (2004) viewed proximal subgoals as possibly including both "target subgoals," or middle-range intermediate subgoals of the kind described by Harackiewicz and Elliot (1998), as well as related, more-close-range sub-subgoals. The present study focused on one likely middle-range target subgoal for college students, namely, college graduation. The reasons for the choice of college graduation as the middle-range target subgoal of interest in the present study were its relatively high importance in a college environment and the fact that the college graduation subgoal was central to the measures of instrumentality and the self-regulation strategies that were tested.

Another important variable in the Miller and Brickman (2004) model is perceived task instrumentality. Perceived task instrumentality was defined as the perception that work on academic tasks

<sup>1</sup> The theoretical basis for Kasser & Ryan's (1993, 1996) classification of aspirations into "intrinsic" and "extrinsic" was the a priori premise in self-determination theory that the pursuit of goals that satisfies the theorized basic needs of competence, autonomy, and relatedness embodies "authentic," or self-determined, motivation, whereas the pursuit of goals emanating from external pressure (e.g., wealth, fame, and image) exemplifies externally controlled motivation (Ryan & Deci, 2000).

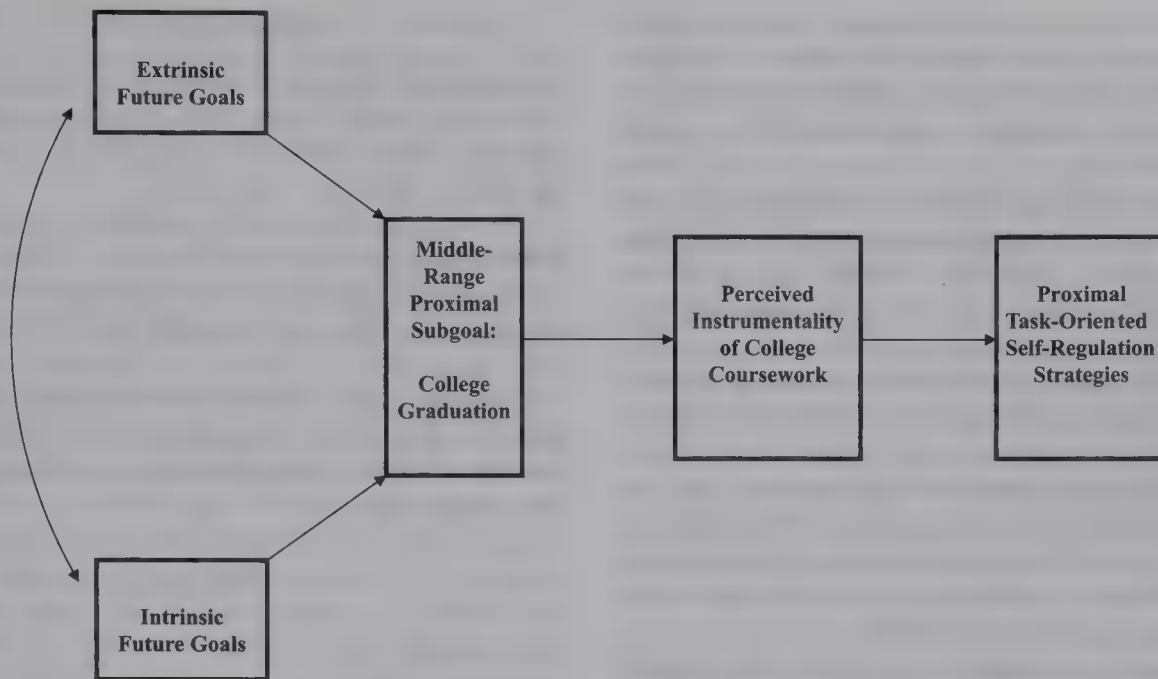

Figure 2. The theoretical model. Extrinsic and intrinsic future goals predict a middle-range subgoal, namely, the college graduation subgoal. The college graduation subgoal, in turn, predicts perceived task instrumentality. Finally, perceived task instrumentality predicts proximal task-oriented self-regulation strategies. The extrinsic and intrinsic future goals correlate.

(i.e., academic course work) is instrumental to one's future.<sup>2</sup> Miller and Brickman (2004) argued that it is the students' perceptions of task instrumentality that transmit the value of their future goals and subgoals to the proximal tasks they are faced with (Miller, DeBacker, & Greene, 1999). They further argued that students are more likely to perceive proximal tasks as instrumental when they have an adaptive system of proximal subgoals leading to personally valued future goals.

Finally, when proximal tasks are perceived to be instrumental, students are more likely to engage in proximal task-oriented self-regulation strategies to accomplish those tasks (e.g., Brickman & Miller, 2001; Greene, Miller, Crowson, Duke, & Akey, 2004; Miller, Greene, Montalvo, Ravindran, & Nichols, 1996). This perspective is in line with Bandura's (1986) observation that personal development is enhanced considerably when individuals connect "distal aspirations with proximal self-guidance" (p. 476). The variables of interest to the present study, along with the theorized relationships among them (Miller & Brickman, 2004), are summarized in the theoretical model (see Figure 2).

Although many of the relationships among the variables depicted in Miller and Brickman's (2004) work are based on research results, some relationships are based mainly on theoretical grounds, as research that specifically connects distal future goals and proximal subgoals is scarce (Husman & Lens, 1999; Locke & Latham, 1990), especially in educational environments. However, the few studies about the relationships between relatively distal goals and relatively proximal subgoals carried out in educational institutions make Miller and Brickman's (2004) hypothesis plausible. For example, in two studies conducted in a college and a high school environment, respectively, Schutz and Lanehart (1994) and Schutz (1997) found, among other things, that the students' distal educational goals (e.g., earn a Master's degree, earn a Doctorate) predicted their proximal educational subgoals

(e.g., "I read textbooks assigned for my class"), and that the distal educational goals indirectly predicted (through the educational subgoals and other variables) the students' grade point averages. Although the distal educational goals tapped by these two studies differed considerably from the personally valued future goals that were of interest in the present study, the findings were in line with Miller and Brickman's (2004) model. Finally, in a study based on an earlier formulation of their motivational model, Brickman and Miller (2001) conducted a qualitative study at an alternative high school and found significant relationships among sociocultural factors and future goals, subgoals, and perceptions of ability among the student participants. These factors were, in turn, related to perceptions of instrumentality of school tasks and to the proximal achievement goals reported. In addition, perceptions of instrumentality were related to self-reports of self-regulation and cognitive engagement and to specific observed patterns of task engagement. Taken together, the results of these studies lend support to Miller and Brickman's (2004) model.

### The Present Study

The purpose of the present study was to test the directional predictions of the portion of the Miller and Brickman (2004) model depicted in the theoretical model (see Figure 2). This portion of the model indicates that students' future goals predict

<sup>2</sup> The construct of perceived task instrumentality is clearly related to Eccles's (1983; Wigfield & Eccles, 2001) "utility value"; however, the constructs differ in their points of emphasis. Utility value refers to an individual's belief about the value of a task or goal object for accomplishing some other end. Miller and Brickman (2004) argued that it is the perception of the instrumentality of a task to future goal attainment that gives the task its value.

their adoption of a college graduation subgoal; that the college graduation subgoal predicts the students' perceptions of task instrumentality; and that the latter, in turn, predicts proximal task-oriented self-regulation strategies (also referred to as "self-regulation strategies").<sup>3</sup>

The present research was important to undertake for a number of reasons. First, it adds to the scarce research on the relationships among future and proximal motivation variables in academic environments, and thus deepens our comprehensive understanding of various facets of motivation. Second, it provides a test of a relatively new, integrated, and directional model of future and proximal motivation and self-regulation (Miller & Brickman, 2004). This study will either provide evidence for the model's hypotheses or suggest ways in which the model could be improved. Third, the current research examines Miller and Brickman's (2004) personally valued future goals differentially, in terms of their extrinsic and intrinsic hypothesized dimensions (Kasser & Ryan, 1993, 1996), an examination not carried out before.

Fourth, the present research examines factors thought to predict perceived task instrumentality. In educational environments, task instrumentality, or the perception among students that the tasks available in school are instrumental to their future, has been found to predict many positive and adaptive learning outcomes (De Volder & Lens, 1982; Greene et al., 2004; Malka & Covington, 2005; Miller et al., 1996; Raynor, 1970, 1974; Simons et al., 2004). Yet very few studies have attempted to answer the question of what predicts task instrumentality. Miller and Brickman (2004) hypothesized that when students have strong, self-determined distal future goals and related proximal subgoals, there is an increased likelihood that students will perceive relevant school tasks as instrumental to goal accomplishment. This study is among the very few to use future goals and a middle-range college graduation subgoal as predictors of task instrumentality. Finally, although (as noted above) task instrumentality has been shown to predict many adaptive educational outcomes, including self-regulation strategies, this study will examine the relationship between task instrumentality and task-oriented self-regulation strategies in a new context of a directional model consisting of interconnected future and proximal motivational variables.

The present study is based on a number of premises. For example, it is important to note that there is no accepted standard in the motivation literature by which a goal can be definitively considered a "future" or a "proximal" goal or subgoal. All goals are, to some extent, future-oriented, and researchers have investigated the relationships between people's *relatively* distal and *relatively* proximal goals and subgoals. In the present study, the most distal goals were the goals assessed by Kasser and Ryan's (2004) Aspirations Index, which tapped intrinsic and extrinsic life goals (e.g., contribution to community, personal wealth). These were referred to in the study as "future goals." A somewhat more middle-range proximal subgoal for these aspirations was that of graduating from college. Graduating from college could be considered for some a step to attaining one or more of the life future goals/aspirations previously mentioned. In the study, this subgoal was referred to as the "college graduation subgoal." The scales used to measure the distal goals and the college graduation subgoal will be described more fully in the Method section, along with all the other scales used in this study.

## Research Questions

Based on Miller and Brickman's (2004) hypothesis about the relationships among future goals, proximal subgoals, task instrumentality, and self-regulation strategies (see Figure 2), the following research questions were asked:

Does the theoretical model depicted in Figure 2 provide an adequate fit of the data?

Do intrinsic and extrinsic future goals have differential relationships with the other variables in the theoretical model (see Figure 2)?

If the theoretical model depicted in Figure 2 provides an adequate fit of the data, how confident can we be that the model provides a plausible variable and path configuration, rather than just a chance fit?

## Method

### Participants

Participants were 421 student volunteers enrolled in 18 sections of a 2nd-year English course, open to all university students and titled Literary Heritage, at a large, southern, urban university. Students in all the sections of this course whose instructors gave permission were asked to volunteer (out of 26 regular on-campus sections, teachers in 18 sections gave their permission for the study). In each section, the maximum enrollment was 35 students. Originally, a total of 422 students volunteered to participate; 1 student, however, filled out the Scantron answer sheet incorrectly and was dropped from the study. The demographic description of the students who were retained in the present study ( $N = 421$ ) was as follows: 88.6% were enrolled as full-time students, 11.4% were enrolled as part-time students, 52.5% were men, 47.5% were women, 13.5% were Black, 75.8% were White, .7% were American Indian/Alaska native, 3.1% were Asian, 1.2% were Mexican-American/Chicano, 1.4% were other Latino, and the rest were "other." Two participants did not report race. ACT scores were as follows: 3.3% reported ACT scores between 11 and 15 (or SAT scores between 500 and 750), 11.9% reported scores between 16 and 18 (SAT scores between 760 and 890), 26.8% reported scores between 19 and 21 (SAT scores between 900 and 1,010), 23% reported scores between 22 and 24 (SAT scores between 1,020 and 1,120), 21.4% reported scores between 25 and 27 (SAT scores between 1,130 and 1,230), and the rest (9.8%) reported scores greater than 27 (SAT scores greater than 1,230). Some students (3.8%) failed to report test scores, and personal discussions with teachers revealed that under special circumstances, students may be accepted without these standardized test scores.

### Procedure

The study was conducted in the students' classrooms. Potential participants were informed of the general nature of the study, as well as of possible adverse effects, and they were told that anonymity and confidentiality would be strictly maintained. Students were offered a small incentive in the form of a candy bar for their

<sup>3</sup> The term "predict" (and its derivatives) in the present study refers to shared variance between the pertinent variables.

participation. After signing a consent form, students were asked to complete the Future-Oriented Student Motivation Survey (FOSS), an instrument containing demographic information as well as four scales, as detailed below.

### Measures

*The Future-Oriented Student Motivation Survey (FOSS).* Participants were administered the FOSS (see sample items in Table 1). This instrument included a short demographic portion as well as four scales measuring different aspects of future- and proximally oriented motivation and self-regulation, as described below.

*The Future Goals Scale.* To measure the strength of personally valued future goals, the Aspirations Index (Kasser & Ryan, 2004) was used in a modified form. The Aspirations Index was chosen for the measurement of personal future goals because it includes seven major (and inclusive) aspirations, and it conceptually divides them into extrinsic and intrinsic aspirations. This allowed for more complexity in the data analysis and in our understanding of whether the intrinsic versus extrinsic nature of the aspirations are predictive of the other variables.

The 2004 version of the Aspirations Index (Kasser & Ryan, 2004) had a 7-point Likert-type scale. It included 35 aspirations representing seven life domains (each life domain being represented by five items). The extrinsic subscale included the life domains of wealth, attractive image, and fame, and the intrinsic subscale included the life domains of health, personal growth, affiliation, and community contribution. For each item representing a goal, three questions were asked: a value question (how important the goal is), an expectancy question (to what extent one expects to accomplish it), and an indirect commitment question (how much of the goal one has accomplished already).

In the present study, two modifications were made to the Aspirations Index: The expectancy question was dropped entirely, since it was not of interest in this study, and the indirect commitment question was changed to a direct commitment question (i.e., how committed one is to reaching the goal). Thus, in the present study, each aspiration item was followed by two questions: a value question and a direct commitment question. Based on the Miller and Brickman (2004) model and social-cognitive theory (Bandura, 1986, pp. 323, 477; Locke & Latham, 1990, p. 124), the value of, and commitment to, goals were thought to be among the most

important goal aspects. Also, the change from an indirect to a direct commitment question reflects the present study's underlying assumption, in line with social-cognitive theory (see Locke & Latham, 1990, p. 5), that people are aware, to a large extent, of their goal commitment levels. The participants responded on a 7-point scale, with 1 denoting *not at all* and 7 denoting *very*. The value and commitment questions were combined and averaged for each of the seven life domains.

*The College Graduation Subgoal Scale.* This scale was developed specifically for the present study and was designed to measure a plausible middle-range mediating subgoal between the distal future goals (as measured by the modified Aspirations Index) and students' perceptions of task instrumentality (i.e., their viewing of their college course work as instrumental for their goal attainment). The scale was modeled after the modified Aspirations Index described above. Following pilot testing, the initial five-item scale was reduced to three items. Each item asked the same two questions that were asked in the modified Aspirations Index: one about value, and one about commitment, for a total of six questions. The participants responded on a 7-point scale, 1 denoting *not at all* and 7 denoting *very*. The responses for all the questions were averaged. The alpha reliability indicated by a pilot study was .97.

*The Perceived Instrumentality Scale.* The Perceived Instrumentality Scale used by Greene et al. (2004) was selected because it was designed to measure instrumentality for school work, which was the variable of interest in this study. Both Greene et al. (2004) and Miller et al. (1999) provided convincing evidence for the reliability and validity of the scale. The scale contains five items measuring perceptions of instrumentality for school work (e.g., "I do the work assigned in this class because my achievement plays a role in reaching my future goal"). Participants responded on a 7-point scale, with 1 indicating *strongly disagree* and 7 indicating *strongly agree*.

*The Task-Oriented Self-Regulation Strategy Scale.* The extent of proximal task-oriented self regulation strategies was measured by a subset of the Motivated Strategies for Learning Questionnaire (Pintrich, Smith, Garcia, & McKeachie, 1991) that included eight learning strategy subscales conducive to college graduation. The eight Motivated Strategies for Learning Questionnaire learning strategy subscales we used were Rehearsal, Elaboration, Organization, Critical Thinking, Metacognitive Self-Regulation, Time

Table 1  
Scales Used in the Present Study With Sample Items and Measures of Central Tendency, Normality, and Reliability

Scale	Sample item(s)	M	SD	Skew	Kurtosis	$\alpha$ rel.
Future Goals Scale <sup>a</sup>	Extrinsic life goal: To be a very wealthy person.	3.95	1.09	-0.04	-0.52	.95
	Intrinsic life goal: To grow and learn new things.	5.85	0.64	-0.78	1.25	.93
College Graduation Subgoal Scale	Goal: To graduate from college.	6.68	0.66	-2.94	10.23	.88
Perceived Instrumentality Scale	I do my course work this semester because. . . My achievement plays a role in reaching my future goals.	5.72	1.33	-1.18	1.14	.92
Task-Oriented Self-Regulation Strategy Scale <sup>b</sup>	I usually study in a place where I can concentrate on my course work.	4.38	0.80	-0.12	0.03	.93

Note. The standard error of skew and kurtosis was .12 and .24, respectively, in most scales.  $\alpha$  rel. = alpha reliability.

<sup>a</sup> This scale is a modified version of the Aspirations Index (Kasser & Ryan, 2004). <sup>b</sup> This scale is a subset of the Motivated Strategies for Learning Questionnaire (Pintrich et al., 1991).

and Study Environment, Peer Learning, and Help Seeking. Participants responded to these items on a 7-point scale, with 1 indicating *not at all true of me* and 7 indicating *very true of me*.

## Results

### *Preliminary Data Analysis*

Prior to conducting the path analysis, we performed a preliminary analysis of the data to gauge whether the data were appropriate for use in a path analysis. A number of two-way contingency table analyses were conducted to evaluate whether the missing values were missing at random, and thus whether they were proportionally distributed by gender, age, student status (part time or full time), race, and expected grade point average. The evidence suggested that the missing data were missing at random. In addition, a before-and-after-mean-substitution examination of instrument reliabilities, measures of central tendency and normality, and correlation matrixes revealed minimal differences. Based on the nature of the data and the results of the preliminary analyses, we used mean replacement for missing values.

**Instrument reliabilities.** Cronbach alpha reliabilities were computed for all scales and subscales on the FOSS instrument to gauge the internal consistency of the scales. A summary of the alpha reliabilities is listed in Table 1. The Future Goals subscales had alpha reliability values of .95 and .93 for the Extrinsic and Intrinsic subscales, respectively, and the alpha reliabilities of the College Graduation Subgoal Scale, the Perceived Instrumentality Scale, and the Task-Oriented Self-Regulation Strategy Scale were .88, .92, and .93, respectively. The reliabilities for the scales in this study were deemed adequate for the present study.

**Measures of central tendencies and normality.** Descriptive information about the variables can be seen in Table 1. The variable with the most pronounced skew and kurtosis was the college graduation subgoal (skew of  $-2.94$ , kurtosis of  $10.23$ ), and that was expected in view of the fact that most college students were likely to indicate a strong desire to graduate from college. Other variables were slightly skewed or kurtotic, as can be seen in Table 1, but their deviation from normality was of small magnitude. In view of the expected deviation from normality in variables related to college graduation goals among the college student population sampled, the variables were left untransformed (see Ullman, 1996, p. 790, for a similar opinion).

For the present path analytic study, we used the maximum likelihood (ML) estimation method. Although the ML estimation is considered fairly robust against small-to-moderate violations of normality (Anderson & Gerbing, 1988; Jöreskog & Sörbom, 1989; McDonald & Ho, 2002), moderate-to-major violations can adversely affect the chi-square statistic that serves as an important measure of model fit. However, the particular way in which the chi-square is affected under conditions of data nonnormality was considered to render the ML estimation method suitable for the present study. According to Curran, West, and Finch (1996), there are two concerns about using the chi-square statistic under conditions of nonnormality: (a) a model might be mistakenly rejected when it is correct, and (b) a model might be opportunistically modified until an acceptable chi-square level is achieved, even though the model might be basically correct and in no need of modification.

In the present study, these two concerns were addressed in a number of ways. First, model fit decisions were not based solely on the chi-square statistic but on other goodness-of-fit indices (GFIs) as well, such as the GFI, the normed fit index (NFI), the nonnormed fit index (NNFI), the comparative fit index (CFI), and the root mean square error of approximation (RMSEA), all of which were reported in the present study.<sup>4</sup> Second, any consideration to remove or add a path was based on strong theoretical grounds rather than on chance trial-and-error opportunities. For example, such considerations were aided by the model parameter estimates, which have been found to be unbiased even under conditions of nonnormality (Curran et al., 1996; Enders, 2001; McDonald & Ho, 2002). Third, care was taken to limit model modifications to very few modifications to prevent "capitalization on chance characteristics of the data" (MacCallum, Roznowski, & Necowitz, 1992, p. 490). Finally, the path analysis was followed by a bootstrap resampling (replication) technique so we could investigate the stability and generalizability of our confirmatory factor analysis model (Efron & Tibshirani, 1998).

**Correlations matrix.** Bivariate scatterplots conducted on pairs of variables chosen at random indicated linear relationships in the data. No curvilinear relationships were observed. Table 2 presents the Pearson moment correlations among the variables of interest. The correlations were very consistent with the Miller and Brickman (2004) model. Nearly all the variables were significantly intercorrelated, and some of the relationships seemed stronger than others, mostly in expected directions. Following the theoretical predictions of Miller and Brickman (2004), future goals correlated significantly with the subgoal of college graduation. At the same time, in line with self-determination theory (Ryan & Deci, 2000), the relationship between extrinsic future goals and the college graduation subgoal ( $r = .12$ ;  $p < .05$ ) seemed to be weaker than the relationship between intrinsic future goals and the college graduation subgoal ( $r = .39$ ,  $p < .01$ ).

As theorized by Miller and Brickman (2004), the college graduation subgoal correlated with task instrumentality ( $r = .42$ ;  $p < .01$ ) as well as with the self-regulation strategies ( $r = .37$ ;  $p < .01$ ), and the self-regulation strategies were highly correlated with task instrumentality ( $r = .58$ ;  $p < .01$ ). In addition, extrinsic and intrinsic future goals correlated with task instrumentality ( $r = .17$  and  $r = .46$ , respectively;  $p < .01$ ), as well as with the self-regulation strategies ( $r = .21$  and  $r = .52$ , respectively;  $p < .01$ ). Again, extrinsic and intrinsic future goals seemed to have a differential relationship to task instrumentality and to self-regulation.

On the other hand, also consistent with self-determination theory and with Kasser and Ryan (1993, 1996), extrinsic and intrinsic goals were not mutually exclusive, and they correlated with each other. Extrinsic future goals correlated with intrinsic future goals ( $r = .33$ ;  $p < .01$ ).

<sup>4</sup> Most fit indexes have strengths and drawbacks. For example, Ullman (1996) reported that the NNFI may underestimate fit in samples with small numbers, although it is not clear how small. In this study, all four indexes were consulted, including the RMSEA indicator, before making judgments regarding model fit.

Table 2  
Correlations Among the Variables in the Present Study

Variable	1	2	3	4	5
1. Extrinsic future goals	1				
2. Intrinsic future goals	.33**	1			
3. College graduation subgoal	.12*	.39**	1		
4. Perceived task instrumentality	.17**	.46**	.42**	1	
5. Task-oriented self-regulation strategies	.21**	.52**	.37**	.58**	1

\*  $p < .05$ . \*\*  $p < .01$ .

### Model Tested

Path analysis was performed, using PROC CALIS (Hatcher, 1994) from SAS/STAT (information on this software can be found at <http://www.sas.com/technologies/analytics/statistics/stat/index.html>), to test the theoretical model (see Figure 2) describing the relationships among four major variables in Miller and Brickman's (2004) model. In the analyses, the ML method of parameter estimation was used, and all analyses were performed on the variance-covariance matrix ( $N = 421$  observations). In the theoretical model (see Figure 2), extrinsic future goals and intrinsic future goals (as measured by the Future Goals Scale) predict the subgoal of college graduation (as measured by the College Graduation Subgoal Scale), which, in turn, predicts task instrumentality (as measured by the Perceived Instrumentality Scale). Finally, perceived task instrumentality predicts task-oriented self-regulation strategies (as measured by the Task-Oriented Self-Regulation Strategy Scale). The extrinsic and intrinsic future goals are modeled as correlating, based on the significant correlations between them in the pilot study and in the present study. Theoretically, as well, these future goals, although shown to lead to differential well-being outcomes, have not been seen as mutually exclusive (e.g., Kasser & Ryan, 1993, 1996).

GFI for the theoretical model, the revised model, and the final model are presented in Table 3, and the bootstrap goodness-of-fit estimates based on the final model (see Figure 3) are presented in Table 4. The chi-square statistic included in Tables 3 and 4 provides a test of the null hypothesis that the reproduced covariance matrix has the specified model structure—in other words, that the model fits the data. Tables 3 and 4 also provide four additional GFIs: the GFI, the NFI (Bentler & Bonett, 1980), the NNFI (Bentler & Bonett, 1980), the CFI (Ullman, 1996), and the RMSEA (Byrne, 2001). GFI, NFI, NNFI, and CFI values of more than .9, and RMSEA values of less than .05 are generally thought to indicate a good fit between the model and the data.

The "null model" in Table 3 represents a hypothetical path model in which none of the variables are related to any of the other variables. This null model chi-square is useful as a baseline against which the chi-square values obtained for the other models can be compared. If the theoretical model achieves a large reduction in chi-square in comparison with the null model (while considering the degrees of freedom), then the theoretical model gains support.

**Estimation of the theoretical model.** Estimation of the theoretical model revealed a significant model chi-square value,  $\chi^2(5, N = 421) = 115.03, p < .001$ , indicating that the observed and

model-implied covariance matrices may be significantly different. Although the value of the GFI was an acceptable .916, the values of the NFI, CFI, and NNFI were .760, .531, and .765, respectively, much lower than the desired  $>.9$ , and the value of the RMSEA was .229, much higher than the desired  $<.05$  value. Taken together, these values indicated that the fit between the model and data could probably be improved.

The path coefficients in the theoretical model (see Table 5) were reviewed to see whether any paths should be deleted or added to improve model fit. The  $t$  values for most path coefficients proved to be statistically significant ( $p < .001$ ), with most  $t$  values exceeding 6.25.<sup>5</sup> Most standardized path coefficients were either equal to or exceeded .28 in absolute magnitude. One path, however, was not significant, namely, the path predicting the college graduation subgoal from the extrinsic future goals (standardized coefficient =  $-.004, t = -.08$ ).

Despite the fact that this path did not reach statistical significance, we decided to leave it in place. This decision was based on three major considerations: First, it was theoretically conceivable that the Future Goals Scale did not capture all the possible extrinsic future goals that people might have. Second, in the literature (e.g., Kasser & Ryan, 1993, 1996), intrinsic and extrinsic goals tend to correlate, albeit at relatively small magnitudes between  $r = .2$  and  $r = .3$ , indicating that people might operate with a mix of goals. Third, we wanted to see what the bootstrap technique would show about all these paths following 200 iterations of the model.

A careful examination of the parameter values in the model, along with a reexamination of the correlations table (see Table 2) and of other theoretical considerations, resulted in the decision to add a direct path predicting perceived task instrumentality from intrinsic future goals. The reasons for adding the path were at least threefold. First, in line with self-determination theory (Deci & Ryan, 2000), the theoretical model parameters indicated that intrinsic, rather than extrinsic, future goals were the ones directly predictive of the college graduation subgoal and, through this subgoal, of perceived task instrumentality. Second, the correlations table (Table 2) indicated a strong and significant relationship between intrinsic future goals and perceived task instrumentality ( $r = .46$ , in comparison with  $r = .17$  for the relationship between extrinsic future goals and task instrumentality). Finally, because it was conceivable (likely) that our subgoal measure did not capture all the variance attributable to intrinsic future goals, we believed that adding a direct path leading from intrinsic future goals to perceived task instrumentality might capture additional variance and improve model fit.

**Estimation of the revised model.** After adding a path predicting perceived task instrumentality from intrinsic future goals, the estimation of the revised model revealed that the hypothesized model, although improved over the theoretical model, still did not fit the data adequately (see Table 3). The chi-square was significant,  $\chi^2(4, N = 421) = 59.12, p < .001$ , indicating that the observed and model-implied covariance matrices were again significantly different. The values of all the indices improved, with the GFI, NFI, NNFI, and CFI at .950, .877, .706, and .882,

<sup>5</sup> These  $t$  tests are statistically significant at the  $p < .05$  level whenever their absolute value exceeds 1.96, at the  $<.01$  level if  $t$  exceeds 2.58, and at the  $<.001$  level if  $t$  exceeds 3.30 (two-tailed tests).

Table 3  
Goodness-of-Fit Indices for the Theoretical, Revised, and Final Models

Model	$\chi^2$	df	p	GFI	NFI	NNFI	CFI	RMSEA
Null model	478.70	10	<.001	0.000				
Theoretical model	115.03	5	<.001	.916	.760	.531	.765	.229
Revised model	59.12	4	<.001	.950	.877	.706	.882	.181
Final model	4.88	3	.181	.995	.990	.987	.996	.039

Note.  $N = 421$  participants. The revised model is identical to the theoretical model, except that a path was added from intrinsic future goals to perceived task instrumentality. The final model is identical to the revised model, except that a path was added from intrinsic future goals to task-oriented self-regulation strategies. GFI = goodness-of-fit index; NFI = normed fit index; NNFI = nonnormed fit index; CFI = comparative fit index; RMSEA = root mean square error of approximation.

respectively. The RMSEA also improved and was .181. Despite the improvement, however, these various measures indicated that the fit was still not adequate. We decided to revise the model again.

Based on similar theoretical rationales that guided the first model revision, we decided to add an additional path predicting task-oriented self-regulation strategies from the intrinsic future goals. The reasons for adding the path were, again, at least three-fold. First, in line with self-determination theory (Deci & Ryan, 2000), the theoretical model parameters indicated that intrinsic, rather than extrinsic, future goals were the ones directly predictive of the college graduation subgoal and, through this subgoal, of perceived task instrumentality and of task-oriented self-regulation strategies. Second, the correlations table (Table 2) indicated a strong significant correlation between intrinsic future goals and

task-oriented self-regulation strategies ( $r = .52$ , in comparison with  $r = .21$  for the relationship between extrinsic future goals and self-regulation strategies). Finally, as it was conceivable (likely) that our perceived instrumentality measure did not capture all the possible variance attributable to intrinsic future goals, we believed adding a direct path leading from intrinsic future goals to task-oriented self-regulation strategies might capture additional variance in self-regulation and improve model fit.

*Estimation of the revised model—2.* Following the second revision of the original theoretical model, the model fit the data quite well (see Table 3). The chi-square was not significant,  $\chi^2(3, N = 421) = 4.88, p = .181$ , indicating that there was no significant difference between the observed and the model-implied covariance matrices. The values of all the fit indices were over .98, as follows: GFI = .995, NFI = .990, NNFI = .987, and CFI = .996. The

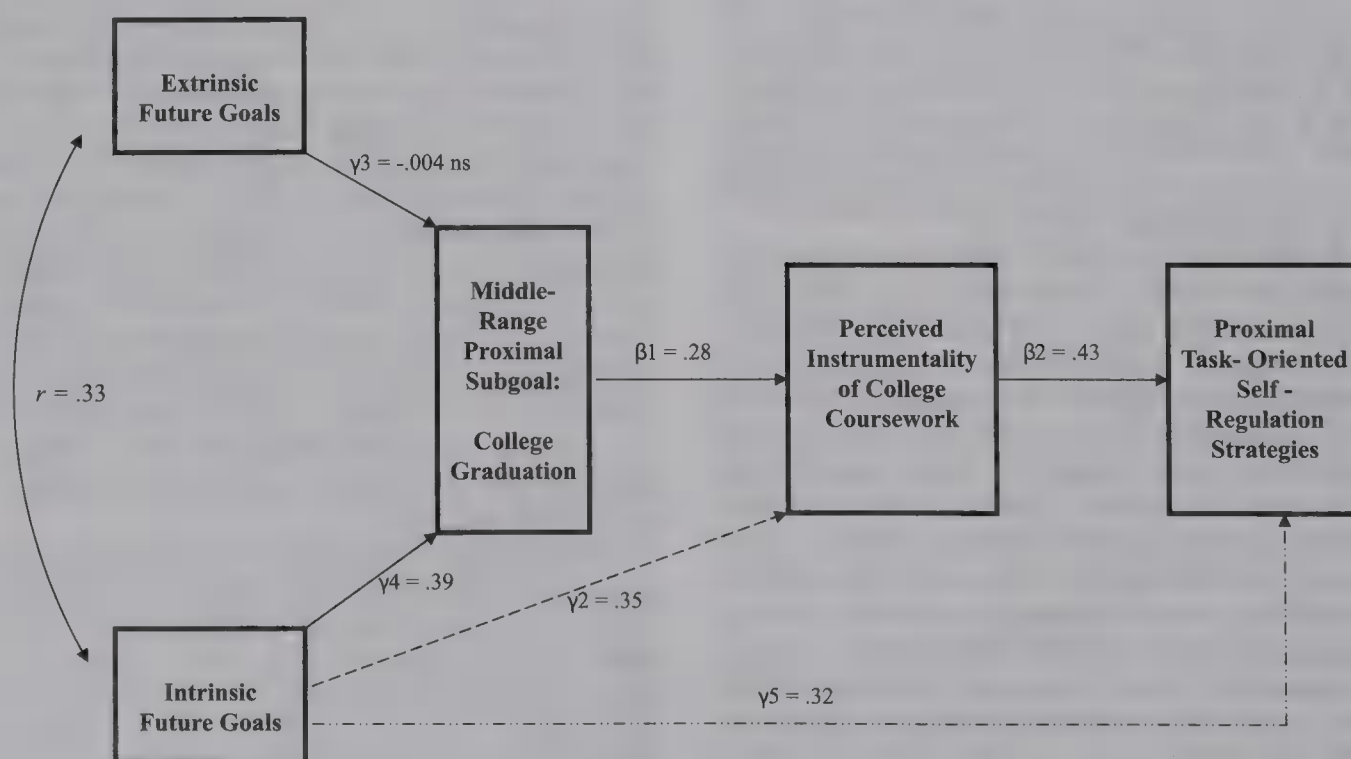

Figure 3. The final model. The broken lines indicate two paths that were added during two subsequent revisions of the theoretical model. These additional paths, predicting perceived task instrumentality from intrinsic future goals and predicting task-oriented self-regulation strategies from intrinsic future goals, constitute the only difference between the theoretical model and the final model. The numbers indicate standardized path analysis coefficients (betas and gammas), with the exception of  $r$ , which indicates the Pearson product-moment correlation between intrinsic and extrinsic future goals. The letters ns indicate that a path is nonsignificant. All significant standardized coefficients had significant  $ts$  at the  $p < .001$  level.

Table 4  
*Bootstrap Goodness-of-Fit Indices for Final Model*

Statistic or index	<i>M</i>	<i>SD</i>	25%	50%	75%	Min., max.
$\chi^2$	7.889	5.681	3.947	6.546	10.715	0.103, 35.237
<i>df</i>	3	3	3	3	3	3
<i>p</i>	.189 <sup>a</sup>	.239	.267 <sup>b</sup>	.088 <sup>b</sup>	.013 <sup>b</sup>	<.001, .991
GFI	.993	.005	.990	.994	.996	.969, .999
NFI	.984	.011	.978	.987	.992	.930, .999
NNFI	.966	.038	.947	.976	.993	.783, 1.022
CFI	.989	.011	.984	.993	.998	.935, 1.000
RMSEA	.053	.036	.027	.053	.078	<.001, .160

*Note.* Bootstrap analysis was based on 200 iterations. Min. = minimum value; max. = maximum value. GFI = goodness-of-fit index; NFI = normed fit index; NNFI = nonnormed fit index; CFI = comparative fit index; RMSEA = root mean square error of approximation.

<sup>a</sup> Average of all probabilities across 200 iterations. <sup>b</sup> Percentile values established by ordering probabilities from high to low values. Values are equivalent to calculating probabilities from the average percentile chi-squares with *df* = 3.

RMSEA was .039, clearly within the <.05 optimal level. It was decided to accept this model as the final model.

In the final model (see Table 5), the path values indicated that task instrumentality was significantly and positively predicted by the college graduation subgoal (standardized coefficient = .28, *t* = 6.25) and by intrinsic future goals (standardized coefficient = .35, *t* = 7.73). Self-regulation strategies were predicted by task instrumentality (standardized coefficient = .43, *t* = 10.19) and by intrinsic future goals (standardized coefficient = .32, *t* = 7.61). Finally, the college graduation subgoal was predicted by intrinsic future goals (standardized coefficient = .39, *t* = 8.10) but not by extrinsic future goals (standardized coefficient = -.004, *t* = -.08, *ns*). Together, the predictors in the final model (see Figure 3) accounted for approximately 84% of the variance in the predicted variables in the model.

### *Bootstrap Analysis*

To investigate the stability and generalizability of our model, we used a bootstrap resampling or, to be more precise, replication technique (Efron & Tibshirani, 1998). In this process we created *B* = 200 new data sets from the original data set and inspected the distribution of several fit measurements.<sup>6</sup> Each new data set contained *N* = 421 observations, and each observation was sampled with a replacement from the original data set. The results of the bootstrap analysis for the final model are presented in detail in Tables 4 and 5.

**Bootstrap model estimation.** The bootstrap analysis based on the final model (see Figure 3) showed evidence of good fit and remarkable stability across the 200 iterations. Table 4 summarizes the mean estimate of the 200 iterations for various model fit indicators as follows: At 3 *df*, the mean chi-square was 7.889, and the mean probability was .189, indicating good fit. Other indicators also showed evidence of good fit, such as the mean GFI (.993), NFI (.984), NNFI (.966), and CFI (.989). The mean RMSEA, slightly above the optimal <.05 at .053, still showed evidence of fair fit (Browne & Cudeck, 1993; MacCallum, Browne, & Sugawara, 1996).<sup>7</sup> Table 4 further shows the values of the various fit

indicators at the 25%, 50%, and 75% quartiles of the bootstrap iterations. At all of these points, most fit indicators showed evidence of good fit. For example, the GFI, NFI, NNFI, and CFI all had values above .94 at all the quartile points. The RMSEA values were between .027 and .053 at most of these quartile points, except for the 75% quartile, where the RMSEA value was .078, higher than the optimal <.05 but still within the fair fit guidelines (MacCallum et al., 1996; see also footnote 7). In addition, the standard deviation across the 200 iterations for most of the indicators was relatively small, indicating good model stability. For example, the standard deviation of the GFI, NFI, NNFI, CFI, and RMSEA fell between .005 and .038. The standard deviation of the chi-square was larger (5.681), and that of the probability was .239, but that was to be expected in view of the fact that some of the variables (notably the college graduation subgoal) deviated from normality. The chi-square statistic is known to be particularly sensitive to "departures from multivariate normality" (Ho, 2006, p. 285).

**Bootstrap parameter estimation.** The mean standard coefficients (betas and gammas) of the 200 bootstrap iterations tended to have nearly identical values to the paths in the final model (see Table 5), thus strengthening our confidence that the final model presents a very plausible explanation of the relationships among the variables of interest.

## Discussion

A directional model based on Miller and Brickman's (2004) model of future-oriented motivation and self-regulation was tested to find out whether the directional ordering of variables was supported by data in an academic setting and whether the predicted influence of future goals on proximal subgoals, task instrumentality, and self-regulation strategies would differ if the extrinsic and intrinsic nature of the future goals was considered. Although we think that our findings clearly address these issues, we want to strike some notes of caution before discussing the interpretations of our findings.

The correlational and predictive methods used in this study do not provide cause-and-effect evidence among the variables examined. Although these nonexperimental methods can provide evidence regarding the plausibility of the proposed paths, model fit in itself is not an indication that the data would not fit other types of relationships or variable configurations. There is a need for future research that continues to investigate the relationships among future goals, proximal subgoals, task instrumentality, and self-regulation strategies using different methodologies, and there is a need for additional experimental research that tests whether observed predictions follow a cause-and-effect pattern.

In addition, although the size of the sample in the present study was adequate for the study's purpose (*N* = 421), the sampling

<sup>6</sup> Efron and Tibshirani (1998) found 200 iterations as adequate in most cases.

<sup>7</sup> MacCallum et al. (1996, p. 134) summarized the RMSEA model fit guidelines, while taking into account Browne and Cudeck's (1993) guidelines, as follows: RMSEA values of less than .05 indicate close fit, values between .05 and .08 indicate fair fit, values between .08 and .10 indicate mediocre fit, and values above .10 indicate poor fit.

Table 5  
*Standardized Coefficients for the Paths in the Theoretical, Revised, and Final Models and in the Bootstrap Analysis of the Final Model*

Path	Standardized coefficient			Bootstrap analysis		
	Theoretical model	Revised model	Final model	Mean st. coeff.	SD	95% CI st. coeff.
Pred. self-regulation strategies from task instrumentality ( $\beta_2$ )	.57 <sup>a</sup>	.57 <sup>a</sup>	.43 <sup>a</sup>	.43 <sup>a</sup>	.03	.37, .48

Pred. task instrumentality from the intrinsic future goals ( $\gamma_2$ )		.35 <sup>a</sup>	.35 <sup>a</sup>	.35 <sup>a</sup>	.05	.26, .44
Pred. college graduation subgoal from extrinsic future goals ( $\gamma_3$ )	-.004, <i>ns</i>	-.004, <i>ns</i>	-.004, <i>ns</i>	.003, <i>ns</i>	.05	-.08, .09
Pred. college graduation subgoal from intrinsic future goals ( $\gamma_4$ )	.39 <sup>a</sup>	.39 <sup>a</sup>	.39 <sup>a</sup>	.38 <sup>a</sup>	.05	.30, .47
Correlation between extrinsic & intrinsic future goals	$r = .33^a$	$r = .33^a$	$r = .33^a$	$r = .33^a$	.04	.26, .40

*Note.* Bootstrap analysis was based on 200 iterations. *ns* denotes a non-significant *t*. The standardized coefficient columns indicate the standardized betas or gammas of the various paths, except for *r*, which indicates the Pearson product-moment correlation. St. coeff. = standardized coefficient; CI = confidence interval; Pred. = predicting.

<sup>a</sup>Significant *t* at the  $p < .001$  level.

method and the study design, involving a convenience sample and data collection during one limited period of time in one university department, limit the generalizability of the study. Additional studies will be needed before findings can be generalized to other disciplines, educational environments, and populations. For example, future research is needed in other disciplines such as business, law, engineering, and medicine to determine whether intrinsic future goals are still the most predictive of adaptive outcomes or whether extrinsic future goals play an important role as well. Additional research is needed at other levels of schooling, such as the elementary and high-schools levels, as well as in private and public schools. With these cautions in mind, we turn now to the discussion and interpretation of our findings.

### The Final Model

The theoretical model in the present study (see Figure 2) was modified by the addition of two paths, and the final model (see Figure 3) showed evidence of good fit with the data. A bootstrap procedure consisting of 200 iterations performed on the basis of the final model added evidence of the model's stability and generalizability.

Consistent with social-cognitive theory (Bandura, 1986) and with Miller and Brickman (2004), future goals had a significant direct and/or mediated relationship to the college graduation subgoal, the perceived task instrumentality, and the self-regulation strategies. Consistent with self-determination theory (Kasser & Ryan, 1993, 1996), the extrinsic and intrinsic nature of the students' future goals had a differential relationship to their subgoal of college graduation, their perceptions of task instrumentality, and their self-regulation strategies. Perceived task instrumentality was directly predicted by the college graduation subgoal and both directly and indirectly by the intrinsic future goals. Self-regulation strategies were directly predicted by task instrumentality and both directly and indirectly by intrinsic future goals. Finally, the college graduation subgoal was directly predicted by intrinsic, but not by extrinsic, future goals.

### Hypothesized Relationships Among the Variables of Interest

The present study's results indicate that Miller and Brickman's (2004) hypothesized mediated relationships among distal future goals, proximal subgoals, perceived task instrumentality, and task-oriented self-regulation are plausible ones: Future goals were found to predict the proximal subgoal of interest to this study, namely, college graduation, and, in turn, the college graduation subgoal was found to predict perceived task instrumentality. Finally, task instrumentality was found to predict task-oriented self-regulation strategies. The additional variance captured by two direct paths added to improve model fit (i.e., the path between future goals and task instrumentality and the path between future goals and task-oriented self-regulation strategies) was not surprising because the measures of the college graduation subgoal and perceived instrumentality used in the present study were unlikely to have accounted for all of the variation in these constructs attributable to intrinsic future goals.

The present study makes a contribution to the literature on goals by providing evidence that distal future goals are significantly related to proximal subgoals, to perceived task instrumentality, and to proximal task-oriented self-regulation, thus strengthening the argument that research on future-oriented and proximal motivation should be integrated (Husman & Lens, 1999; Kauffman & Husman, 2004). Also, the present study is among the first to test a specific hypothesis involving personally valued future goals and their predicted relationship to proximal subgoals, to task instrumentality, and to task-oriented self-regulation strategies in an educational setting. Results show a plausible directional path between the adoption of personally valued future goals, proximal subgoals, task instrumentality, and task-oriented self-regulation strategies at the college level.

### Task Instrumentality

The present study's contribution to our understanding of factors predicting task instrumentality deserves particular attention. Perceptions of task instrumentality have been found to have many

adaptive educational outcomes (e.g., Greene et al., 2004; Raynor, 1970, 1974; Vansteenkiste, Simons, Lens, Soenens, et al., 2004), including the adaptive task-oriented self-regulation strategies tested in the present study. Until recently, most studies of perceived task instrumentality have used task instrumentality as the predictor variable, which has made it hard to find out what factors may predict task instrumentality itself (e.g., Malka & Covington, 2005; Simons, Dewitte, & Lens, 2003). Because of the importance of perceptions of task instrumentality in educational environments, there has been a need to find factors that may predict task instrumentality.

Recently, Greene et al. (2004) found classroom-level context variables (perceived task meaningfulness, autonomy support, and mastery evaluation) to be important direct and indirect predictors of perceived task instrumentality. Earlier, Maehr and Midgley (1991) suggested that students' motivation regarding the tasks that they are asked to engage in may be influenced not only by classrooms and teachers, but also by school-level factors. In three case studies, Brickman and Miller (2001) found that students' past experiences in the larger sociocultural context (e.g., at home, at school, with peers, and through the media) were related to their perceptions of task instrumentality, possibly through the students' future goals, proximal subgoals, and perceptions of ability.

The present study found that the college graduation subgoal was a direct predictor of task instrumentality, and that intrinsic future goals were both direct and indirect (through the college graduation subgoal) predictors of task instrumentality. According to the directional model tested, the present study suggests that the students' own college graduation subgoal and future goals were the variables predicting perceived task instrumentality. Thus, to the possibility that task instrumentality may be predicted by community-, school-, and classroom-level factors, we may now add the possibility that task instrumentality may also be predicted by the students' own intrinsic future goals and by their own proximal subgoals, such as the college graduation subgoal.

### *Intrinsic Versus Extrinsic Future Goals*

The present study found that a focus on intrinsic, rather than extrinsic, future goals may be more predictive of the adoption of robust proximal subgoals, of adaptive perceptions of task instrumentality, and of the adoption of task-oriented self-regulation strategies in college environments. Kasser and Ryan (1993, 1996) have noted earlier that not all personally valued future goals were equally likely to predict similarly positive outcomes. These researchers found that extrinsic future goals were associated with diminished well-being in the present, while intrinsic future goals were associated with relatively high levels of well-being in the present. The present study is among the first to find evidence for a similar differential effect of extrinsic and intrinsic future goals in a different context than the studies mentioned above, namely, when future goals were used to predict proximal subgoals, task instrumentality, and task-oriented self-regulation strategies among college students.

Although this finding should be treated with caution until further evidence emerges, there is some indirect evidence that lends it additional support. Writing from a goal orientation theoretical perspective, Nicholls, Patashnick, and Nolen (1985) examined whether high school students' (relatively proximal) personal goals

in school were related to their perceptions of what the (relatively distal) aims of education should be. Despite the fact that Nicholls et al.'s (1985) construct of "aims of education" differed considerably from the present study's construct of personally valued future goals, their findings were in the same direction as those in the present study. The authors found that high school students who perceived the aim of education to be furthering one's wealth and status tended to have maladaptive personal school goals such as work avoidance, and they also tended to have ego, rather than task, orientations. On the other hand, students who perceived the aim of education to be commitment to society or understanding of the world tended to have adaptive personal school goals such as working hard, and they also tended to have task, rather than ego, orientations. These results are consistent with self-determination theory (Ryan & Deci, 2000).

In the present study, consistent with Kasser and Ryan (1993, 1996), personally valued intrinsic future goals were the pivotal point in predicting many positive factors, both directly and indirectly (e.g., college graduation subgoal, task instrumentality, task-oriented self-regulation strategies), whereas personally valued extrinsic future goals failed to produce a statistically significant relationship with the college graduation subgoal, the primary mediator for the rest of the model. The personally valued intrinsic future goals that the present study tested were individual growth, relationships, community involvement, and health. The personally valued extrinsic future goals tested were wealth, fame, and appearance.

### *Educational Implications*

Although the correlational nature of our study prohibits drawing causal conclusions, the clarity of the findings and the strong theoretical basis of the directional ordering underlying the model tested lead us to speculate about possible educational implications, should the model be supported by additional research using various methodologies (e.g., longitudinal studies) and by experimental research in particular. It is interesting to note that it may be the types of interventions hinted at below that provide experimental support for the model's validity. We see three areas with potential implications: the importance of students clarifying their future goals and subgoals, the utility of perceived instrumentality as a diagnostic tool for important motivation problems, and the importance of emphasizing the intrinsic goals of schooling. Each of these ideas is elaborated below.

*Clarification of personal goals and subgoals.* The high dropout rates in high schools and colleges in the United States, especially among poor students (National Center for Educational Statistics [NCES], 2004), raise the possibility that at least some of the students do not have an awareness of their own goals, have not done much thinking about aligning their future and proximal goals and subgoals in any coherent way, and have no idea where they are headed. The present research has indicated that the direction in which goals affect students may be from distal intrinsic future goals to proximal subgoals. Based on this knowledge, it may be possible to design goal-based interventions targeting at-risk students that would explain how a goal system works, help students identify their own long-term intrinsic goals, and set subgoals along the way, leading to the more distal future goals. For students with

no adaptive long-term intrinsic goals, it may be possible to design an intervention to foster such beneficial goals.

Students at risk of dropping out of school are often offered courses in remedial or study skills, and yet most college students enrolled in these remedial courses end up dropping out of school (NCES, 2004). The present study points to a possible reason. Study skills are the types of things that make up the self-regulation strategies that students normally set for themselves, such as study in a quiet place, study with a friend for a test, and summarize main ideas to oneself, among others. In the present study, these types of strategies were shown to be directly predicted by perceived instrumentality, directly and indirectly predicted by intrinsic future goals, and indirectly predicted by the college graduation subgoal. It may well be the case that students exhibiting problems in the self-regulation strategy area may have motivational problems that start with a lack of awareness of the larger goals at hand. Rather than focus on teaching a battery of standardized study skills, remedial programs may be more beneficial if they first helped students clarify or develop intrinsic future goals and proximal subgoals leading to their personal future goals, and if they then helped students perceive their work as instrumental toward achieving their goals. With their future goals and subgoals in place, and with well-developed perceptions of instrumentality, students may be in a much better position to act on improving their task-oriented self-regulation strategies or study skills.

*Perceived task instrumentality as an indicator.* The contribution of perceived task instrumentality to achievement and to other motivational factors in academic settings has been widely recognized (e.g., Brickman & Miller, 2001; Greene et al., 2004; Miller & Brickman, 2004; Raynor, 1970, 1974; Vansteenkiste, Simons, Lens, Soenens, et al., 2004). For example, Miller and Brickman (2004) as well as Greene et al. (2004) suggested that perceived task instrumentality may function as a helpful incentive when a student has to do school work that is not inherently pleasurable. The present study suggests that evident problems with perceived task instrumentality may serve as an early warning signal that can alert teachers and parents that their student may be having a more serious motivational problem. The present study found that the paths leading to perceptions of task instrumentality from intrinsic future goals and from the college graduation subgoal were significant. In other words, problems with task instrumentality (e.g., not seeing the reason why one should do a school assignment or thinking that all assignments are worthless) may be related to much larger problems, such as a lack of appropriate subgoals (e.g., school graduation), a lack of appropriate intrinsic future goals, or a combination of these factors. Accordingly, when a student exhibits signs of weak or nonexistent task instrumentality, educators should take it seriously and look beyond the specific assignment that was not turned in to identify other possible underlying problems. Such problems may include not only the student-level goal factors identified by the present study, but also classroom- and school-level factors identified by other studies (e.g., Brickman & Miller, 2001; Greene et al., 2004; Maehr & Midgley, 1991). In dealing with perceived task instrumentality problems on the part of students, educators may start by addressing student-level factors, such as discussing the student's intrinsic future goals and their subgoal or subgoals. If needed, educators may then widen their intervention to include classroom-, school-, and community-level factors, to the extent possible.

*Focus on intrinsic future goals.* The present study has found that the major predictor of a positive educational goal system and task instrumentality is the adoption of intrinsic, rather than extrinsic, future goals. Although these results need to be treated with caution until more evidence becomes available, it is interesting to note that, whereas some studies have identified possible drawbacks to extrinsically focused future goals (e.g., Kasser & Ryan, 1993, 1996; Nicholls et al., 1985; Ryan et al., 1999; Vansteenkiste, Simons, Lens, Soenens, et al., 2004), there are almost no studies identifying drawbacks to intrinsically focused future goals. In the present study, the paths from the intrinsic future goals to all other variables were significant, whereas the path from extrinsic future goals linking this variable to the rest of the mediated model was not significant. At the same time, intrinsic and extrinsic future goals were not mutually exclusive. In the two models tested, extrinsic and intrinsic future goals had a moderate correlation, implying a relationship. The implication may be that, although people may have a mix of extrinsic and intrinsic future goals, in order to be successful in an academic environment, they may need a stronger focus on intrinsic goals, such as personal growth, relationships, community involvement, and health.

For educators, these findings imply that they should encourage students to excel not by pointing out how much higher their salaries would be if they graduated from their respective schools, but by pointing out, for example, how much the students would know or how they might be able to contribute to society. The great importance accorded to educational improvement in the United States (e.g., United States Department of Education, 1983, 1994, 2001), coupled with the recognized potential of intrinsic future goals in particular, and of intrinsic factors in general, to improve schools, has already led many educators and researchers to design programs of school improvement that emphasize intrinsic elements (e.g., Brown, 1997; Huffman & Hipp, 2003; Mertens, Flowers, & Mulhall, 2001; Newmann & Wehlage, 1993; O'Hair & Odell, 1995; O'Hair & Reitzug, 1997; Raywid & Oshiyama, 2000; Wenger & Snyder, 2000).

## Conclusion

The purpose of the present study was to test a portion of the Miller and Brickman (2004) model of future-oriented motivation and self-regulation to find out whether students' distal future goals are related to their adoption of proximal subgoals, to their perceptions of task instrumentality, and to their task-oriented self-regulation strategies. The results supported Miller and Brickman's (2004) hypothesis that future goals predict the adoption of proximal subgoals, that proximal subgoals predict perceptions of task instrumentality, and that perceived instrumentality, in turn, predicts task-oriented self-regulation strategies. In line with self-determination theory (Kasser & Ryan, 1993, 1996), the present study also found that future goals had a differential relationship to the variables of interest: Although extrinsic future goals were not significant predictors of the college graduation subgoal, the primary mediator for the rest of the model, intrinsic future goals were significant direct predictors of the college graduation subgoal and direct and indirect predictors of perceptions of task instrumentality and of task-oriented self-regulation strategies. This finding suggests that, pending additional research, educators should consider emphasizing intrinsic future goals (and other intrinsic factors),

such as personal growth, meaningful relationships, and community contributions, in school environments to better facilitate the development of students' future goals, proximal subgoals, perceptions of task instrumentality, and task-oriented self-regulation strategies. In addition, the results of the present study indicate that the Miller and Brickman (2004) model of future-oriented motivation and self-regulation may serve as a basis for designing goal-based interventions to help at-risk students stay in school and succeed academically.

In their article about future-oriented motivation and self-regulation, Miller and Brickman (2004) urged that

those interested in proximal research issues and those with more future-oriented research agendas need to join forces in studying the phenomenon of academic motivation and self-regulation, and in planning interventions designed to improve the lives of the countless students who fail to see the relevance of schooling in their lives. (p. 29)

By finding a meaningful and significant connection between future goals, proximal subgoals, perceived task instrumentality, and task-oriented self-regulation strategies, the present study lends additional support to the need for continued attempts at integrating future-oriented and proximally oriented motivation and self-regulation.

## Addressees of Performance Goals

Albert Ziegler, Markus Dresel, and Heidrun Stoeger  
University of Ulm

As performance goals aim to both procure acknowledgment of one's abilities and to avoid revealing a lack of one's abilities, the authors hypothesized that students hold specific performance goals for different addressees and that there are specific correlational patterns with other motivational constructs. They analyzed a data set of 2,675 pupils (1,248 boys and 1,426 girls) attending Grades 8 and 9 (mean age = 15.0,  $SD = 0.97$ ). The students completed a questionnaire consisting of 12 items measuring performance approach goals and 12 items measuring performance avoidance goals. In each subset, 4 groups of addressees were differentiated: parents, teachers, peers, and the acting individual him/herself. Additionally, several external criteria were measured. The authors concurrently tested theory-driven, structural equation models. Incorporating all 24 items, the best-fitting model was a multitrait-multimethod model, which posited 2 factors for approach and avoidance goals and 4 addressee factors. While performance goals addressing parents showed relationships to maladaptive motivational and learning patterns, performance goals addressing classmates and self showed relationships to adaptive motivational and learning patterns. The relationships between performance goals addressing teachers and external criteria were rather weak and unsystematic.

**Keywords:** motivation, achievement goals, addressees of performance goals, approach and avoidance performance goals

There is a general consensus that in scholastic contexts, achievement goals have a decisive influence on achievement behavior (cf. Pintrich & Schunk, 2002). In the research literature, two distinctions have been made to categorize the different goals students hold (e.g., Elliot & McGregor, 2001; Pintrich, 2000). The primary distinction differentiates between mastery goals (sometimes referred to as *learning goals*) and performance goals (Ames, 1992; Dweck, 1986; Maehr & Midgley, 1991). Students who focus on making progress in learning and developing their knowledge, competences, or abilities seek mastery goals. Students who aim to accumulate acknowledgment of their performances or attempt to avoid having others perceive their lack of abilities are committed to performance goals. Empirical studies indicate that mastery goals and performance goals have different types of effects on learning and achievement behavior. For instance, differential correlations with academic self-concept (Skaalvik, 1997; Vrugt, Oort, & Zeeberg, 2002), effort expenditure (Meece, Blumenfeld, & Hoyle, 1988; Wolters, 1998), depth of learning processes (Ames & Archer, 1988; Meece et al., 1998; Wolters, 2004), task value (Bong,

2001), text anxiety (Linnenbrink, 2005; Middleton & Midgley, 1997), and achievement (Elliot & McGregor, 2001; Harackiewicz, Barron, Tauer, Carter, & Elliot, 2000) could be confirmed. Whereas mastery goals have proven to be adaptive in just about all studies, the findings on performance goals were somewhat less distinct. Some studies showed negative relationships between performance goals and the aspects of student learning mentioned above; other empirical studies found no relationships or even positive relationships (see Elliot, 1999, for an overview). In order to explain these ambiguities associated with performance goals, a second distinction was introduced. It considers the positive versus negative valence of the state or situation the goal setting process focuses on (Elliot, 1999; Elliot & Harackiewicz, 1996; Elliot & Sheldon, 1997; Middleton & Midgley, 1997). This distinction differentiates between an approach component—in the sense of an approach toward desirable states or situations—and an avoidance component—in the sense of an avoidance of undesirable states or situations. Within the past decade, this distinction has been established for performance goals, whereby it could be shown that approach goals and avoidance goals are positively correlated, but nonetheless separate components (Elliot & Harackiewicz, 1996; Elliot & Sheldon, 1997; Middleton & Midgley, 1997). Research on the consequences of performance approach goals and performance avoidance goals showed that the above-described negative effects of performance goals can primarily be ascribed to the avoidance component. It is negatively related to scholastic performance, academic self-concept, task value, and effort expenditure as well as positively related to test anxiety, maladaptive attributional style, and surface processing (e.g., Dresel, 2001; Elliot & Church, 1997; Elliot & McGregor, 2001; Elliot & Sheldon, 1997; Middleton & Midgley, 1997; Pintrich, 2000). The findings pertaining to the approach component were, in contrast, less consistent (for an

overview, see Midgley, Kaplan, & Middleton, 2001). Although positive correlations could be confirmed with achievement and academic self-concept, findings regarding task value, effort expenditure, and depth of learning processes varied between null and moderately positive correlations (Harackiewicz, Barron, Pintrich, Elliot, & Thrash, 2002; Kaplan & Middleton, 2002; Midgley et al., 2001).

Recently, researchers also made a distinction between an approach and an avoidance component within mastery goals, resulting in a full  $2 \times 2$  framework of achievement goals (Elliot & McGregor, 2001; Pintrich, 2000). It can be argued that students may also focus on the undesirable state of misunderstanding and not mastering a task and therefore adapt their learning in accordance with avoidance goals. Research has provided some evidence that mastery avoidance goals are associated with a more negative motivational set than mastery approach goals and a more positive motivational set than performance avoidance goals (Elliot & McGregor, 2001).

In the present work, we focus on performance approach and performance avoidance goals. More specifically, our aim was to test whether the structures and the relationships of performance goals depend on the various social referents to which they are addressed. Our work is anchored in the two-component definition of performance goals advanced by Elliot (1999)—namely social comparison and appearance—and we are particularly interested in the significance of the appearance component. As stated above, performance goals focus on the demonstration of competence or, in the case of the avoidance component, the attempt to avoid having others perceive a lack of competence. One can presume that an important role is played by who these “others” are. Furthermore, we hypothesized that addressee-specific performance approach and avoidance goals may be related to other constructs in a specific manner, reflecting the relevance of the specific social instance on which the current goal is focused. We hold the view that a systematic consideration of the various addressees of performance approach goals and performance avoidance goals may lead to a deeper understanding of the goals that students hold in the social context of scholastic learning as well as the consequences of goal setting processes.

### Addressee-Specific (Interpersonal) Performance Goals

In the context of scholastic learning, there are three major groups of important others: teachers, classmates, and parents. Teachers define most of the learning tasks, provide help, bring about formal and informal performance situations (such as tests or oral classroom questions), define the major standards for evaluation of performances, provide students with verbal (public, face-to-face) or written feedback, and often react to students' performances with different emotions. In other words, they are typically the most salient persons in the classroom setting. Classmates are typically copresent in all performance situations but are absent in face-to-face conversations with the teacher. They define a second bundle of standards (e.g., “being good in school is uncool”) and reward or punish students with verbal statements and with emotions such as sympathy or antipathy. Parents are commonly absent in all classroom learning and performance situations. However, they provide students with a learning environment at home, occasionally undertake learning activities together with their child,

codefine standards for the evaluation of school performances, often reward good performances and punish bad performances, and react in emotional terms. To summarize this list of characteristics (for an overview, see Wentzel, 1998, 1999), these groups of important others share different situations with the student, provide different standards of performance evaluation, bring up rewards and punishments based on presumably different standards, and place different expectations on the student.

Based on the assumption that students are aware of these differing standards, reward systems, and expectations, it is plausible that the salience of one's competence or competence deficits are weighted differently for different groups of important others. As the aim to either have one's competences acknowledged or avoid having others perceive a lack of one's competences builds the core concept of performance goals, this assumption implies that students probably differ in their performance goal setting process among different groups of important others. In other words, different performance goals may be directed to different addressees. For instance, a student may be concerned about the perceptions of his or her parents, but he or she may not care about the perceptions of his or her classmates.

The significance of addressees for learning and the goal setting process has also been investigated by other authors and has resulted in some degree of empirical validation (Harris, 1995; Wentzel, 1998, 1999); nevertheless, to this point a systematic evaluation has not yet been attempted. This is also reflected in the measuring instruments that have been used to assess performance goals. Although some measuring instruments explicitly include teachers or pupils as addressees of learning and achievement behavior (e.g., Midgley et al., 1996; Miller, Greene, Montalvo, Ravindran, & Nichols, 1996), no systematic examination on the influence of the individual addressees was ever undertaken. In some cases, only classmates (e.g., DeBacker Roedel, Schraw, & Plake, 1994) or teachers and classmates (e.g., Midgley et al., 1996) were included in the items as addressees, but not parents.

Empirical indications for addressee-specific goals have been supplied by Urda and Mestas (2006) with their qualitative study. In structured interviews, they questioned pupils about their individual reasons for pursuing performance approach goals (e.g., “I want to do better than other students in this class”) and performance avoidance goals (e.g., “It is important to me not to do worse than other students in this class”). An analysis of the answers disclosed a variety of purposes behind students' goal pursuits. Included here were purposes that were directed toward specific addressees, such as wanting to please parents or to silence naysaying peers. These were categorized by the authors as interpersonal performance goals (see also Wentzel, 1998, 1999). Additional support for addressee-specific goal setting processes are inherent in findings that show that individual goals depend on classroom goal structures, general instructional formats, parents' goals, and peer group standards (e.g., Church, Elliot, & Gable, 2001; Grusec & Goodnow, 1994; Kinderman, 1993).

### Intrapersonal Performance Goals: The Individual Him/ Herself as an Addressee

In addition to important others, we assume that the acting individual may him/herself be an addressee of performance goals. In our opinion, intrapersonal or self-addressed performance goals

are goals that imply a normative standard of competence definition (resulting from the performances of others), but—in contrast to performance goals that are directed to external addressees—they do not associate a positive appearance to others with a desirable state or a negative appearance to others with an undesirable state. Examples for intrapersonal performance goals could be wanting to be satisfied with oneself for attaining good grades, wanting to be happy about one's performances, or wanting to avoid dissatisfaction with bad performances (see Urdan & Mestas, 2006, for a similar conceptualization of intrapersonal performance goals and preliminary qualitative evidence for their existence).

In contrast to interpersonal performance goals, which are assumed to trigger the use of techniques to control the appearance component (such as selective communication or the utilization of excuses), intrapersonal performance goals may result in the application of self-enhancement processes with self-confidence as an anticipated state. The anticipated state is also the decisive characteristic that differentiates intrapersonal performance goals from mastery goals: While the former focus on the consummate magnitude of one's competence and its appreciation, the latter focus on the growth or development of one's competences (see Dweck, 1999). As a consequence, intrapersonal or self-addressed performance goals should act as a guide in the procurement of information to protect self-confidence and self-worth, while mastery goals should act as a guide in the search for realistic information to enable optimal learning (see Dweck & Elliott, 1983). Nevertheless, we expect that self-addressed performance goals are more closely related to mastery goals than externally addressed performance goals. This is because self-addressed performance goals, plausibly, not only underlie a normative standard but also an absolute standard of competence evaluation (resulting from the task requirements), similar to mastery goals for which an intrapersonal standard (resulting from one's past performances) and/or an absolute standard is applied (see Ames, 1992; Dweck, 1999; Maehr, 1989; Elliot & McGregor, 2001; cf. Pintrich & Schunk, 2002).

### Research Questions and Hypotheses

The main purpose of the present study was to test whether performance approach and avoidance goals can be specified for four addressee groups (parents, teachers, classmates, and the student him/herself) in the context of scholastic learning. To validate this distinction, we analyzed the associations between addressee-specific performance goals and other motivational and emotional facets of the learning process, namely mastery goals, academic self-concept, achievement, effort expenditure, depth of learning processes, task value, and test anxiety.

Four major hypotheses were tested: (1) Performance goals are differentiated for different addressee groups within both performance approach goals and performance avoidance goals. (2) Performance goals are divided in performance approach goals and performance avoidance goals within each addressee group. (3) The simultaneous incorporation of the distinction between an approach and an avoidance component as well as the distinction among different addressees results in a better representation of performance goals than the exclusive incorporation of only one of the two distinctions. (4) Different addressee-specific goals show different relationships to mastery goals and other aspects of the learning process.

## Method

### Participants

Analyses of the present study are based on a sample that is part of the calibration sample for a new measuring instrument, the Ulm Motivational Test Battery (Ziegler, Dresel, Schober, & Stoeger, 2005). Our analyses included all eighth graders and ninth graders in the calibration sample for which a complete data set was amassed (1,354 eighth graders and 1,321 ninth graders). The 2,675 students were attending one of the three major types of German public schools: Hauptschule (lowest achievement level; 34.7%), Realschule (average achievement level; 33.5%) and Gymnasium (highest achievement level; 31.8%).<sup>1</sup> Students participated voluntarily in the investigation and had obtained permission from their parents. The investigation was conducted as a paper-and-pencil test during regular classroom instruction, and took about 45 min to complete. The mean age of the students came to 15.0 years ( $SD = 0.97$ ), 53.3% of whom were girls.

### Measuring Instruments

**Performance goals.** To assess the performance approach goals and performance avoidance goals specifically being addressed to various members of the learning environment or the acting individual him/herself, we used a previously developed questionnaire. Research (Schober, Ziegler, & Dresel, 2001; see also Ziegler & Stoeger, 2002) confirmed that this measuring instrument is consistent with prevailing quality criteria such as internal consistency and criterion validity. The 24-item questionnaire systematically crosses the two performance goal components (approach and avoidance component), with the four major addressee groups relevant in the scholastic context. These addressee groups are the parents of the students, their teachers, their classmates, and the acting individual him/herself. Crossing the two components with the four addressee group results in eight combinations. For each of these combinations, the questionnaire contains three items that focus on different anticipated reactions of addressees (e.g., taking notice of the competences of the student, evaluating these competences, reacting in an emotional manner). All items were measured with a 6-point Likert-type scale, ranging from 1 (*I disagree completely*) to 6 (*I agree completely*). All 24 items are listed in Table 1, accompanied by their respective goal component and addressee group.

**External criteria.** To examine whether addressee-specific performance goals are associated with other constructs in a specific manner, we measured seven external criteria that are known to be related to performance goals. Unless specified otherwise in the following, all items on the respective measurements were presented along a 6-point Likert-type scale, ranging from 1 (*I disagree completely*) to 6 (*I agree completely*). To assess mastery goals, we

<sup>1</sup> In the German public school system following the fourth grade, pupils are allocated to one of the three school types named above on the basis of academic achievement. The curriculum in a Hauptschule lasts for a period of 5 years, the curriculum in a Realschule lasts 6 years, and in a Gymnasium—depending on federal state—students study for 8 or 9 years. The first two school types train students for future occupations (apprenticeship); the third serves as preparation for university studies.

Note. *N* = 2,675. Scale range for all items: 1–6.

used the 6-item scale that is also included in the questionnaire for the assessment of the goals stated above (Schober et al., 2001). In this scale, mastery goals are exclusively operationalized as approach goals (sample item: "In school I want to learn as much as possible"). Academic self-concept was assessed with the scale "Confidence in one's own competence" (Dweck & Henderson, 1988). This scale consists of four item pairs containing two statements corresponding to a positive self-evaluation and a negative self-evaluation. The two poles of a 6-point answer scale are formulated as statements (e.g., "I am not sure that I am good enough to be successful in school" and "I am sure that I am good enough to be successful in school"). Achievement was operationalized by averaging report card grades obtained in the subjects German (native language), English (foreign language), and mathematics on the previous year's report cards. The German grading scale ranges from 1 (very good) to 6 (unsatisfactory). The resulting scale was recoded, so that a higher score represented better achievement. Effort expenditure was measured with a 12-item scale (Ziegler et al., 2005). The scale offers insight into the amount of effort students apply to their learning (sample item: "I spend a lot of time at home doing school exercises"). Depth of learning processes was operationalized with a scale developed by Gold and Souvignier

(2004) and was assessed with seven items (sample item: "While studying I try to find examples to match the material"). Task value was measured with a scale consisting of three items that were drawn from Ziegler et al. (2005). This scale primarily measures the utility of learning (sample item: "The things you learn in school are useful later on"). Test anxiety was measured with a six-item scale, which had been evaluated in earlier studies (Schober et al., 2001; Ziegler et al., 2005). Similar to the performance goal measures, test anxiety items were associated with specific addressees (sample item: "When I think about school, I am afraid that my teacher will notice that I can't do something").

### Analyses

To test several concurrent hypotheses concerning the differentiation of performance goals among addressee groups and their relation to external criteria, we performed confirmatory factor analyses using LISREL 8.51 (Jöreskog & Sörbom, 2001). The analyses were based on covariance matrices and used maximum-likelihood estimation. In each set of analyses, several theory driven models were compared against one another using chi-square tests

Table 2

(e.g., Byrne, 1998). Hypothesized and alternative models are described in the Results section.

## Results

### *Descriptive Statistics*

Table 1 contains means and standard deviations for all 24 performance goal items. Scale consistencies, descriptive statistics, and zero-order correlations for the external criteria examined are presented in Table 2.

### *Model Tests Regarding Approach and Avoidance Components*

The first confirmatory factor analysis set was performed to test whether a differentiation among the four addressee groups could be confirmed in the performance approach component, in the performance avoidance component, or in both (Hypothesis 1). We conducted two separate sets of analyses, each including the 12 respective, component specific items (see Table 1). Figure 1 depicts the three models that were tested for each component: (a) total rating factor, in which all 12 items load on one latent variable; (b) others-self, in which the three self-addressed items load on one latent variable and the remaining nine items that address others load on a second latent variable; (c) four addressee groups, in which the parents, teacher, classmates, and self-items load on their respective latent variables, resulting in four correlated, addressee-specific factors. This is the hypothesized model.

As displayed in Table 3, the results indicate clear support for a distinction among several addressees regarding performance approach goals. In contrast to the two alternative models, the hypothesized four addressee groups' model revealed a good fit to the performance approach item data.<sup>2</sup> Model comparisons indicated that the hypothesized model provided a better fit than the other two models. Moderate to large factor correlations were observed among the three latent factors concerning other persons (see Table 4). For self-addressed performance approach goals, we found small to moderate correlations with externally addressed performance approach goals, whereby the highest correlation was observed with the parent factor.

Results concerning the performance avoidance component revealed a somewhat different pattern: Although model comparisons disclosed significant advantages for the hypothesized four addressee groups model, the model fit differences among the three models were smaller than those found for performance approach

goals. Additionally, none of the three models revealed an adequate fit to the data. Finally, correlations calculated for the latent factors of the hypothesized model were generally larger for performance avoidance goals than those for performance approach goals. In one case, a correlation greater than 1 was even calculated, resulting in a latent factor correlation matrix, which was not positive definite (see Table 4).

Inspection of the modification indices of the performance avoidance models revealed strong evidence for substantial correlated errors between two item pairs (modification indices  $> 200$ ), which focus on identical anticipated reactions of addressees (Items Av-P3 and Av-T3 are both focusing on reproaching; Items Av-P1 and Av-T1 are both focusing on taking notice of deficient competences; see Table 1). Within an exploratory framework, we repeated the analyses with setting the two error correlations free. Significant correlated errors for the two item pairs were estimated for all three models ( $\delta_s = .22$ – $.24$  and  $\delta_s = .25$ – $.26$ , respectively). Results indicated an acceptable model fit for the four addressee groups model and slightly worse model fits for the alternative models (see Table 3). The hypothesized differences between the models respecting data fit remained significant. The latent factor correlation matrix of the four addressee group model was now positive definite and consisted of slightly lower values than in the model without correlated errors (see Table 4). Nevertheless, latent correlations among the four addressee factors respecting avoidance goals were still substantially larger than those respecting performance approach goals.

### *Model Tests Regarding Addressee Groups*

To additionally test whether the approach-avoidance distinction is also valid for specific addressees (Hypothesis 2), we conducted modeling within the four addressee groups. For each addressee group, we tested two models with the respective three approach and three avoidance items: total rating factor, in which all six items load on one latent variable, and approach-avoidance, in which the approach items load on one latent variable and the avoidance items load on another. This is the hypothesized model.

For parents, teachers, and classmates as addressees of performance goals, results clearly indicate that a distinction between approach and avoidance goals holds true. For all three groups, the

<sup>2</sup> Because the sample size is very large, in this and all subsequent analyses significant chi-square tests are not unexpected and should not be interpreted as an indicator of bad model fit (see Byrne, 1998).

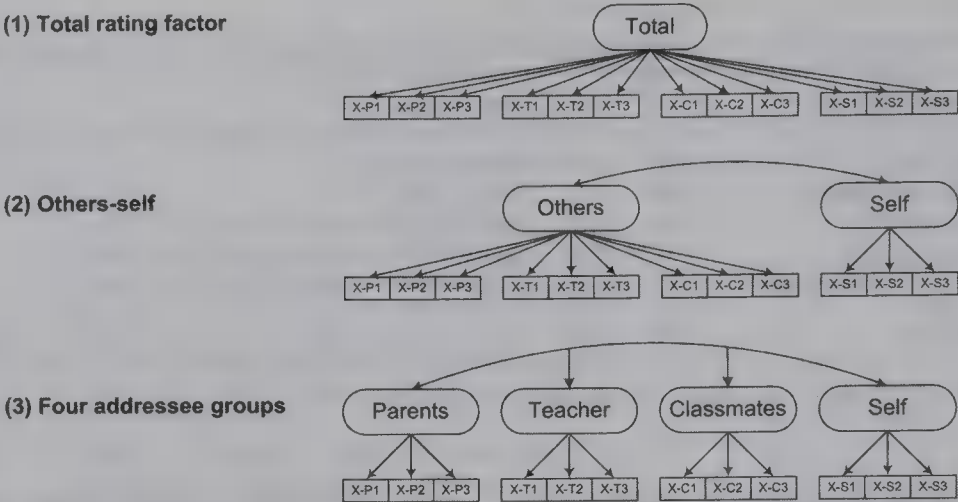

Figure 1. Hypothesized models for both performance approach and performance avoidance components. For reasons of clarity, uniquenesses are not included in the figure. First set of analyses (1): X = performance approach item. Second set of analyses (2): X = performance avoidance item. P = parents item; T = teacher item; C = classmates item; S = self-item.

approach–avoidance model revealed sufficient fit indices for the most part (parents: comparative fit index [CFI] = .99, Tucker–Lewis index [TLI] = .99; teacher: CFI = .92, TLI = .85; classmates: CFI = .94, TLI = .89), whereas the total rating factor model resulted in lower fit indices (parents: CFI = .94, TLI = .91; teacher: CFI = .89, TLI = .82; classmates: CFI = .86, TLI = .76). Model comparisons revealed for all three addressee groups that the two component model fits the sample data significantly better than the model featuring a total rating factor,  $\chi^2(1) > 136.7, ps < .001$ . As expected, the modeling revealed moderate to high latent correlations between performance approach goals and performance avoidance goals. The correlations between the two latent factors were  $\varphi = .70$  for parent-related goals,  $\varphi = .79$  for teacher-related goals, and  $\varphi = .66$  for goals that are directed toward classmates. In contrast to these three external addressee groups, results regarding goals that are directed to the acting person him/herself are somewhat different: Both hypothesized models fit the data in a comparable manner (total rating factor model: CFI = .94, TLI = .90; approach–avoidance model: CFI = .94, TLI = .89). The differences between the fit indices were not significant,  $\chi^2(1) =$

0.4,  $p = .52$ . Moreover, the latent correlation between the two components in the approach–avoidance model was very high ( $\varphi = .92$ ). Obviously, the approach–avoidance distinction is less evident for self-addressed performance goals than for externally addressed performance goals.

Model Tests Incorporating All Facets

In the next step, we tested a series of models that incorporated all 24 items (Hypothesis 3; see Figure 2): approach–avoidance, in which the 12 approach items load on one latent variable and the 12 avoidance items load on another; four addressee groups, in which the parents, teacher, classmates, and self-items (six items in each case) load on their respective latent variables, resulting in four correlated addressee-specific factors; approach–avoidance by four addressee groups, in which eight component and addressee-specific factors were defined, each having three items; and approach–avoidance and four addressee groups, in which the 12 approach items and the 12 avoidance items load on their respective latent variables and additionally in which the parents, teacher,

classmates, and self-items load on their respective four addressee factors. This is the multitrait-multimethod model (MTMM model), which posits two loadings for each item on a component factor and on an addressee factor (refer to Byrne, 1998).

The fit indices for the four models are presented in Table 5. In line with our expectations, models that exclusively posit approach and avoidance components or the four addressee groups do not fit the data nearly as well as models that incorporate the influences of both performance goal components and addressee groups. The model crossing approach and avoidance components with addressee groups (resulting in eight latent variables) fits substantially better, but the model with the best fit is the MTMM model, which simultaneously posits two component factors and four addressee factors. CFI and TLI values above .90 also indicate that the approach-avoidance and four addressee groups model is the only model with an adequate fit to the data.<sup>3</sup>

Latent factor correlations for the MTMM model are displayed in Table 6. These correlations specify the relationship between the approach and avoidance components controlled for several addressee groups and vice versa. Results reveal that the approach component and the avoidance component correlate high positive, when the addressee groups of performance goals are controlled for. On the other hand, moderate to high latent correlations between performance goals addressing differential social referents emerged when the distinction between approach goals and avoidance goals was controlled for. The latent correlation between parent-addressed goals and teacher-addressed goals was particularly high. However, latent correlations incorporating the acting individual him/herself as the addressee of performance goals were substantially lower, especially for associations with teacher- and classmate-directed goals.

### *Relationships With External Criteria*

To examine relationships between addressee-specific performance goals and the external criteria observed (Hypothesis 4), we expanded the model with the best fit (approach-avoidance and four addressee groups) to a regression model with free regression paths from both component factors as well as from each addressee group factor to one latent endogenous variable. We ran the analysis separately for each of the seven external criteria as an endogenous variable. Central to our hypotheses are the regression coefficients of the structural model, which are displayed in Table 7.

While systematic influences of several addressees were controlled in these models, the prediction of the seven external criteria from performance approach goals and performance avoidance goals provided highly valid estimations of associations with other motivational variables. Here, a distinct pattern occurred for approach and avoidance goals. Performance approach goals predicted mastery goals, academic self-concept, effort expenditure, depth of learning processes, and task value in a positive sense. In contrast, performance avoidance goals demonstrated weak to moderately negative relationships with mastery goals, academic self-concept, achievement, effort expenditure, and task value. Additionally, performance avoidance goals showed a clearly positive relationship to test anxiety, while performance approach goals could not predict this significantly.

The regression coefficients of the four factors corresponding to the four addressee groups are relevant for our hypothesis that addressee specific relationships with external criteria do exist. Since the model structure incorporates a control for approach and avoidance components, these are estimates of the unique effects of each of the four addressee groups, in that they partial out the above described global effects of the two goal components. As hypothesized, results indicate different relationships, contingent on the addressees of performance goals for all external criteria. Of particular interest for the achievement goal literature may be the regression coefficients associated with mastery goals. Here, our results reveal a negative association with parent-addressed performance goals and positive associations with classmate-addressed and self-addressed performance goals, whereby the latter was especially high. Similar relationships occurred for task value—a supplemental negative effect was, admittedly, observed for teacher-directed performance goals. With respect to academic self-concept and achievement, self-addressed performance goals again served as a significant positive predictor. Academic self-concept was additionally predicted by parent-directed performance goals in a negative sense. While predicting effort expenditure, goals that were addressed to classmates or to the student him/herself turned out to be positive predictors, while regression coefficients for parent- and teacher-addressed goals were insignificant. The regression of depth of learning processes again displayed a differential importance for several of the addressees: While parent- and classmate-addressed goals did not predict the extent of deep learning processes, teacher- and self-addressed goals predicted it positively. Finally, a differential pattern also appeared for test anxiety: It was positively associated with performance goals, which are directed toward parents, and negatively associated with performance goals aimed at one's self. While the respective regression coefficient was relatively low for the individual him/herself as an addressee of performance goals, a substantially higher coefficient was observed for parents as addressees of performance goals.

<sup>3</sup> Analogous to the models in the avoidance component, large modification indices respecting correlated errors between the above named items were observed (modification indices > 126.7). Since the fit of the MTMM model was satisfactory before the correlated uniquenesses was set free, and the fit of the remaining models would not improve substantially through such exploratory framed specifications (CFIs < .89, TLIs < .88), we did not include them in the models.

## Discussion

The work at hand pursued the central idea that performance goals could be addressee specific. This idea is based on the differing situations, standards, reward systems, expectations, and emotional reactions relating to various groups of important others, whereby in the context of scholastic learning, parents, teachers, and classmates are of prime relevance (Wentzel, 1998, 1999). Moreover, we assumed that the individual him/herself could be an addressee of performance goals (refer also to Urdan & Mestas, 2006). The study aimed to clarify whether the differentiation among these four addressee groups holds true for performance approach and performance avoidance goals and to test whether an additional and systematic consideration of addressee groups results in a better representation and understanding of performance goal processes (including associations with other motivational and emotional facets of learning) than the exclusive incorporation of the approach-avoidance distinction.

With respect to our first hypothesis, it was shown that different addressee groups comprise separate factors for performance goals. This was clearly valid for performance approach goals and to a somewhat lesser degree also for performance avoidance goals. For both components, a four-addressee-group model offers a significantly better model fit than either a total-rating-factor model or a model that differentiates between interpersonal and intrapersonal

performance goals (see Urdan & Mestas, 2006). One can conclude that pupils differentiate among various addressees while building up performance goals. Thus, they distinguish to whom they want to appear to be competent or not to appear to be incompetent. Moreover, they often hold a separate class of performance goals, which do not target how they appear to other persons, but are exclusively intrapersonal in nature. Noteworthy is that, for performance avoidance goals, the four addressee factors were more closely associated with each other than those for performance approach goals. Moreover, differences between the hypothesized model and the alternative models were less substantive for performance avoidance goals. This could be an indication that the anticipation of positive states (which is inherent in approach goals) is more specifically focused on certain positive outcomes (e.g., the impression given to a specific person that one is competent) than the anticipation of negative states (a constituent of avoidance goals), which apparently is focused more generally on the negative appearance of student competences.

The results concerning our second hypothesis revealed that the distinction between an approach and an avoidance component holds true for all external addressee groups of performance goals. For intrapersonal performance goals, the validity of the approach-avoidance distinction did not hold. One can infer that the approach-avoidance distinction is definitely relevant when students aim to be viewed by others as competent or aim to avoid being viewed as incompetent, but this distinction is less striking when the appearance component is absent, in other words when students pursue the intrapersonal goal of being confident or not being confident about their competences (cf. Elliot, 1999).

Testing models with all facets of performance goals resulted in clear indications that simultaneous incorporation of the distinction between an approach and an avoidance component as well as the distinction among different addressees result in a better fit to sample data than the exclusive application of only one of the two distinctions. According to these results, taking different addressees into account provides researchers with a better understanding of goal setting processes. A particularly good fit resulted for the MTMM model, which independently posits two component factors

<sup>a</sup> not significant.

and four addressee factors. These findings imply that addressee specification could be a distinction, similar in importance to the approach-avoidance distinction, while being relatively independent from it. Accordingly, results clearly revealed that the differentiation among various addressees can hardly replace the approach-avoidance distinction in achievement goal theory. Addressee specification could, rather, provide a justifiable supplement and refinement of the existing theoretical framework. For instance, when researchers are interested in associations between performance goals and other motivational and emotional facets of learning, these should be systematically controlled for several addressees. In fact, a contribution to the existing literature on achievement goal theory may be provided by the results compiled on the associations of performance approach goals and performance avoidance goals with external criteria under systematic control for addressee-specific influences. Our addressee-controlled results may help to clarify the contrary association patterns regarding performance approach and performance avoidance goals with various aspects of adaptive and maladaptive learning (for an overview, see Midgley et al., 2001).

With our forth hypotheses, we focused on addressee-specific associations of performance goals with the above designated external criteria. As expected, different addressee groups of performance goals were of different importance with respect to relationships with mastery goals and other aspects of the learning process. For external-addressed performance goals, small to moderate regression coefficients were observed, indicating a differential pattern with respect to the different addressee groups. Similar to performance avoidance goals (Ames & Archer, 1988; Wolters, 2004), parent-addressed goals correlated negatively with mastery goals, academic self-concept and task value, and positively with test anxiety. With respect to the population here under investigation, eighth and ninth graders, it appears as though performance goals that are oriented on appearances vis-à-vis one's parents are less adaptive. Although the significance of parents in scholastic learning processes is common knowledge, this finding demonstrates that their relevance to goal setting processes is widely underexplored. This is also reflected in existing measurement instruments for the assessment of achievement goals, which only seldom incorporate parent-addressed goals. One implication of the present study is that measurements of goals should increasingly

focus on parents as a relevant social factor for performance goals. A more adaptive pattern resulted in conjunction with performance goals addressing classmates: These were positively associated with several facets of an adaptive learning process, namely mastery goals, effort expenditure, and task value. In contrast to performance goals addressing parents and classmates, teacher-directed goals were associated more weakly, and in a contradictory manner, according to the criteria assessed in our study. A positive association with depth of learning processes and a negative association with task value were the only significant effects, but were, with respect to direction, inconsistent with one another. One reason for this pattern might be that although teachers define learning tasks and evaluation standards, their rewards and punishments may often be of less relevance for the average 15-year-old than standards defined by peers or parental rewards and punishments (Harris, 1995).

In terms of relationships with external criteria, self-addressed goals may define a separate class of performance goals: In comparison to other addressee-specific goals, especially parent-addressed goals, a contrary pattern of regression coefficients emerged. Self-addressed performance goals were positively associated with all aspects of adaptive learning and were negatively related with our indicator of maladaptive learning, namely test anxiety. A further examination of self-directed performance goals would be an interesting task for future research. Good cause for this is provided not only by the results mentioned above but also by a remarkably high positive association with mastery goals. Here one would want to clarify whether self-addressed performance goals build up, as assumed in the present work, a separate class of performance goals or alternatively whether they combine aspects of performance goals and mastery goals, for example concerning the underlying normative and absolute standards of evaluation.

As the present study was conducted in Germany, it would be desirable to replicate the results in other countries in order to examine possible cultural differences. However, when doing so readers should be aware that the items in the questionnaire may be interpreted differently by an Anglo/American population. For example, pretests showed that different wordings used to refer to academic performance such as "I am good" and "I get a good grade" are not interpreted as being different by German students but might be understood to have disparate meanings by students in

other countries. A more serious limitation of the present study is that no disclosures could be made on the genesis of the addressee specification of performance goals. The population from which we derived our sample was made up of pupils in the eighth and ninth grades of German public schools and therefore represented a relatively narrow age range. We assumed that persons in this age group have already completed the developmental process of differentiation among performance goals concerning important others. Nevertheless, very little is known about this developmental process. Although initial findings support the assumption that, with increasing age, performance goals are increasingly differentiated with respect to different addressees (Stoeger, 2002), further research to enlighten this developmental process is clearly needed.

# Achievement Goals and Achievement During Early Adolescence: Examining Time-Varying Predictor and Outcome Variables in Growth-Curve Analysis

S. Serena Shim  
Northern Arizona University

Allison M. Ryan and Carolyn J. Anderson  
University of Illinois at Urbana–Champaign

The present study advances understanding of (a) the development of achievement goals, (b) the changing association of achievement goals and achievement over time, and (c) the implications of changes in achievement goals for changes in achievement over time. African American and European American adolescents' ( $N = 588$ ) achievement goals and subsequent achievement were assessed at 4 time points (fall and spring of 6th and 7th grades) and modeled using growth-curve analytic techniques. There was an overall decline in all 3 types of achievement goals (mastery, performance-approach, and performance-avoidance goals), because of within-year rather than between-year decreases. The association between mastery goals and achievement was null at Time 1 and then positive at the following 3 time points. The association between performance-approach goals and achievement went from negative to null across time. Changes in students' goals, as well as their initial levels of goals, were particularly important in understanding how mastery goals foreshadow achievement. The implications of the findings for both theory and practice are discussed.

**Keywords:** achievement goal orientation, middle-school transition, adolescence, motivation, achievement

A prominent construct in current theoretical models of motivation is the achievement goal (Wigfield, Eccles, Schiefele, Roeser, & Davis-Kean, 2006). Research using an achievement-goal framework has flourished in recent years. Extant work has primarily focused on the relation of achievement goals to a variety of educationally relevant outcomes and the influence of different instructional contexts on achievement goals (Wigfield et al., 2006). There has been little longitudinal research on achievement goals. Thus, our understanding of how achievement goals change across time and the implications for students' achievement across time is incomplete. Therefore, in this article, we examine the developmental processes of achievement goals and achievement with a longitudinal research design and growth-curve analytic techniques that incorporate changes in the predictor variables (i.e., achievement goals) as well as the outcome variable (i.e., achievement). We begin with an overview of theory and research on the achievement-

goal construct, highlighting why a longitudinal analytical approach is appropriate and will advance understanding of the nature of achievement goals and the consequences of achievement goals for achievement. We then discuss our approach and rationale for the three key questions that guide our longitudinal investigation: (a) What is the nature of the development of achievement goals? (b) Does the association between achievement goals and achievement change across time? and (c) Do changes in achievement goals have implications for changes in achievement?

## Overview of Theory and Research on Achievement Goals

Achievement goals represent different orientations toward academic competence that students often have in achievement settings (see Elliot, 2005, for a review). Researchers have distinguished between a mastery goal (a focus on developing academic competence) and performance goals (a focus on demonstrating academic competence to others, especially via social comparisons of relative ability; e.g., Ames & Archer, 1988; Dweck & Leggett, 1988; Harackiewicz & Elliot, 1993; Nicholls, 1989). Researchers have found it is important to distinguish performance goals as approach oriented or avoidant oriented (Elliot & Church, 1997; Middleton & Midgley, 1997; Skaalvik, 1997). A performance-approach goal concerns a focus on demonstrating high competence and gaining positive judgments from others. A performance-avoidance goal concerns a focus on avoiding the demonstration of incompetence and preventing negative judgments from others. For example, a student with a mastery goal might reflect on such questions as "Am I learning? Have I improved my skills?"; a student with a performance-approach goal might reflect on such questions as "Do I look smart? Did I do better than others?"; and a student with a performance-avoidance goal might reflect on such questions as "Do I look dumb? Did I perform worse than others?"

Different goals set in motion disparate cognitive, emotional, and behavioral processes (Dweck & Leggett, 1988; Elliot, 2005). Achievement goals are viewed as a proximal influence on competence-relevant processes and outcomes; they are a precursor to behavior (i.e., why a student does something precedes whether, if, and how they actually do it; Elliot & Church, 1997). Personality or dispositional factors are postulated to partially explain individual differences in achievement goals (e.g., Dweck & Leggett, 1988; Elliot, 1999; Harackiewicz, Barron, & Elliot, 1998). However, theorists describe achievement goals as fluctuating in relation to different experiences in learning environments (Ames, 1992; Maehr & Midgley, 1996). Experimental work has been successful in orienting students to pursue different achievement goals (e.g., Butler, 1993; Elliot & Harackiewicz, 1996; Newman & Schwager, 1995). Observational work that links classroom experiences to personal goals is also evidence for this viewpoint (Linnenbrink, 2005; Patrick, Anderman, & Ryan, 2002; Turner, Meyer, & Midgley, 2003). Thus, achievement goals are conceptualized as dynamic and changing in relation to features of the context.

The analytic methods used to study the effects of goals have not captured the changing nature of achievement goals. The vast majority of quantitative research on the effects of achievement goals (i.e., goals as predictors) falls into one of three designs: (a) goals and outcomes measured together at one point in time (e.g., Middleton & Midgley, 1997; A. M. Ryan & Pintrich, 1997; Wolters, 2004), (b) goals measured at Time 1 and outcomes measured at Time 2 (e.g., Elliot, McGregor, & Gable, 1999; Grant & Dweck, 2003; Harackiewicz, Barron, Tauer, & Elliot, 2002), and (c) goals measured at Time 1 and outcomes measured at Time 1 and Time 2 (e.g., McGregor & Elliot, 2002; Senko & Harackiewicz, 2005; Shim & Ryan, 2005; Stipek & Gralinski, 1996). We propose that growth-curve analytic techniques that incorporate the changing nature of achievement goals are well suited to theoretical conceptualizations of achievement goals and provide a more complete understanding of the development of achievement goals and the consequences for achievement.

### What Is the Nature of the Development of Achievement Goals?

Our first concern is to understand the nature of the development of achievement goals during early adolescence. Prior longitudinal research examining the development of achievement goals during early adolescence (i.e., goals as outcomes) has assessed achievement goals at two time points and found that a mastery goal declines and a performance-approach goal increases across the transition to middle school (E. M. Anderman & Midgley, 1997; L. H. Anderman & Anderman, 1999).<sup>1</sup> However, analyzing change across two time points provides a limited understanding of the development of achievement goals. At least three time points are needed to document a trend (Rogosa, 1988). Further, these studies have assessed achievement goals at one point in different grades, and thus, within- and between-school-year changes have not been disentangled. Changes in motivation over time within the same classroom environment may be different from changes that occur as students move into new classrooms or school environments. Such information is particularly important regarding the transition to middle school, given the long-standing concerns that middle-level schools are a major source of declines in motivation during

early adolescence (see Eccles, Lord, Roeser, Barber, & Jozefowicz, 1997; Juvonen, Le, Kaganoff, Augustine, & Constant, 2004). Are there normative declines in achievement goals in progress prior to the transition? Are declines in achievement goals seen in the beginning of the middle-school year, or do they unfold during the first year in middle school? The present study addresses such unanswered questions and provides a more complete understanding of the nature of change in goals during early adolescence by estimating growth trajectories across four time points (data were collected in 6-month increments in the fall and spring of both sixth and seventh grades, spanning the transition to middle school). We examine the overall trend in development across the four time points as well as investigate the within- and between-year patterns of change that contribute to any documented trends.

We subsequently examine interindividual differences to see whether growth trajectories vary across individuals and, if so, whether some of this variation can be explained by gender and/or race. Findings regarding gender differences in achievement goals are not entirely consistent, but when differences are found, girls tend to be more mastery oriented than boys (e.g., Ablard & Lipschultz, 1998; Freeman & Anderman, 2005; Kenney-Benson, Pomerantz, Ryan, & Patrick, 2005; Meece & Holt, 1993; Nolen, 1988), and boys tend to be more performance oriented than girls (e.g., L. H. Anderman & Anderman, 1999; Middleton & Midgley, 2002; Roeser, Midgley, & Urdan, 1996; A. M. Ryan, Hicks, & Midgley, 1997; Stipek & Gralinski, 1996). There has been far less research on race differences in achievement goals, but some research suggests that African American students may be higher in mastery (e.g., Kaplan & Maehr, 1999; Middleton & Midgley, 2002) as well as performance-approach and performance-avoidance goals (Middleton & Midgley, 2002). However, given the limited longitudinal analyses of achievement goals, we do not know if gender and race relate to the development of goals across time or if the relation of gender and race to achievement goals changes across time. The relations of gender and race might differ when students are in elementary versus middle school, as both gender and ethnicity take on new significance. Gender and race differences may emerge or grow stronger as students cognitively mature and reflect on their identity in more complex ways during adolescence.

### Does the Association Between Achievement Goals and Achievement Change Over Time?

Prior research on achievement goals and achievement has yielded inconsistent findings and spurred debate as to the consequences of achievement goals for achievement (Harackiewicz, Barron, Pintrich, Elliot, & Thrash, 2002; Midgley, Kaplan, & Middleton, 2001). The consequences of achievement goals may change as students mature and move through the educational system (see Midgley et al., 2001). Growth-curve models that treat

<sup>1</sup> Several other studies have examined the relation of achievement goals across two time points (e.g., Middleton, Kaplan, & Midgley, 2004; or Gehlbach, 2006), but the focus was on stability across time (i.e., correlations, beta coefficients), not normative developmental trends (i.e., mean level differences between the two time points were not reported). Because our study focuses on developmental patterns, we do not review these stability coefficients here.

achievement goals as time-varying predictors are well suited to examine the changes in the achievement goal–achievement relation. To examine the implications of achievement goals for subsequent student achievement, we incorporate the measurements of achievement goals at all four time points into our models for achievement and test whether the effects of goals on subsequent achievement are consistent over time. Because a performance-avoidance goal has consistently been found to be negatively associated with achievement, our focus is on the associations between mastery and performance-approach goals and achievement. When effects are found, a mastery goal is positively related to achievement for younger students (e.g., Kaplan & Maehr, 1999; Midgley & Urdan, 1995; Roeser et al., 1996; A. M. Ryan, Patrick, & Shim, 2005; Wentzel, 1993; Wolters, Yu, & Pintrich, 1996; but see also Pajares, Britner, & Valiante, 2000; Pajares & Valiante, 2001; Pintrich, 2000; Skaalvik, 1997, for studies documenting no relation).<sup>2</sup> A mastery goal has consistently been found to have no association with achievement for college students (see Harackiewicz, Barron, Pintrich, et al., 2002, for a review). A performance-approach goal has been found to have no association with achievement for younger students (e.g., Pajares et al., 2000; Pajares & Valiante, 2001; but see A. M. Ryan et al., 2005, for a study documenting a negative relation). However, a performance-approach goal has consistently been found to have a positive association with achievement for college students (see Harackiewicz, Barron, Pintrich, et al., 2002, for a review). As students advance through the educational system, the context becomes more competitive (e.g., grading on a curve), and a mastery goal may be less adaptive, whereas a performance-approach goal may be more adaptive for achievement. The transition to middle school represents such a change in context (see Eccles, 2005, for a review), and thus, our longitudinal study spanning this transition is at an appropriate time to examine whether the association of achievement goals to achievement changes.

### Do Changes in Achievement Goals Have Implications for Changes in Achievement?

Motivational research most typically emphasizes interindividual effects, compared with intraindividual effects. Interindividual effects concern variations between students and document if high or low scores on an aspect of motivation, compared with other students, explain variation in engagement or achievement. Intraindividual effects concern the changes in individuals' motivation that occur across time and document if such within-individual fluctuations are important for changes in engagement or achievement. Our first two research questions concern interindividual analyses and identify general patterns across students (the first pertaining to the development of goals and the second pertaining to the associations of goals to achievement across time). However, we expect that there is variability in those general patterns between students. For example, we may document a general decline in mastery goals over time, but not all students will conform to this general pattern. Our third research question concerns intraindividual analyses and examines the implications for achievement of varying within-individual patterns of change in achievement goals. Examining intraindividual effects contributes to a more complete understanding of how motivational beliefs may support or hinder achievement across time.

Prior research has incorporated intraindividual change in achievement goals using residual scores (Time 2 goal scores are regressed on Time 1 goal scores; see Meece & Miller, 2001). Another approach used was the creation of change scores (goal scores at Time 2 minus goal scores at Time 1; see Gehlbach, 2006). Such studies concluded that when a mastery goal declines, various aspects of engagement, as well as achievement, decline, and when a mastery goal increases, engagement and achievement increase. Another similar study examined change scores in students' perceptions of teacher encouragement of different achievement goals and found that when students' perceptions of their teacher emphasizing mastery goals declined from one year to the next, their engagement and achievement declined (Urden & Midgley, 2003). No effects for performance goals were found in any of these studies; however, performance-approach and performance-avoidance goals were not distinguished (Gehlbach, 2006; Urden & Midgley, 2003) or not examined (Meece & Miller, 2001).

Such research recognizes the importance of intraindividual change in achievement goals but does not provide a complete understanding of the implications of changes in students' achievement goals. These analytic approaches examine the direction of change but do not incorporate the general level of achievement goals during the two time periods (e.g., in Urden & Midgley's 2003 study, approximately three fifths of students were categorized as "no-change," and within this group were students whose goal scores were high, medium, or low at both time points). In contrast, we use growth-curve models to capture both the level of achievement goals and the pattern of change within students across four time points. We include two predictors: students' achievement-goal scores at Time 1 (termed baseline score) and deviations from their Time 1 achievement-goal scores (termed *DevT<sub>i</sub>* score). A baseline score, the most typical predictor examined in longitudinal analyses indicates whether students' achievement goals at the beginning of the study predict the growth trajectory in achievement over time. The *DevT<sub>i</sub>* scores indicate whether gains and losses from Time 1 scores are also important. By including both predictors, we are able to ascertain whether changes in achievement goals, beyond students' initial levels of achievement goals, contribute to an understanding of students' achievement trajectories during early adolescence.

### Overview of the Present Research

In summary, in the present study, we use a longitudinal design and growth-curve analytic techniques to advance understanding of

<sup>2</sup> Achievement refers to student grades, not standardized tests. This is appropriate to compare patterns between younger students in public schools and college students, as college students do not routinely take standardized tests, and thus, research on college students' achievement goals and achievement has examined grades as a measure of achievement. In addition, the present study uses grades as an indicator of student achievement, so it makes sense to focus the literature review in this way. Further, in our review of the relationship between achievement goals and achievement, we examine the zero-order correlations, not the unique effects of goals above and beyond other achievement-related variables in multiple regression models. These types of multiple regression models vary greatly across studies and include variables that may be mediators of the relationship between achievement goals and achievement, which is not the focus of the present study.

(a) the normative patterns of development of achievement goals, (b) the potentially changing association of achievement goals and achievement over time, and (c) the implications of within-individual changes in achievement goals (with attention to both direction of change and level of goals) for changes in achievement over time. Our longitudinal design includes four measurements of achievement goals in the fall and spring of sixth and seventh grades. Consistent with our conceptualization that achievement goals predict achievement, our four measurements of achievement (i.e., grade-point average [GPA] computed from report card grades) were collected at the end of the corresponding semesters and thus encompass achievement that extends beyond the measure of achievement goals. When we examined the associations of achievement goals to achievement across time, we controlled for prior achievement (i.e., fifth-grade GPA) because relations between achievement goals and achievement are reciprocal and we wanted to examine the effects of achievement goals on achievement above and beyond the contribution of prior achievement history (see Brophy, 2005; Senko & Harackiewicz, 2005, for a discussion of these issues).

## Method

### Procedure

The data were collected as part of the University of Illinois at Urbana-Champaign Adolescent Transitions Project, which is a 2-year longitudinal study examining changes in academic and social adjustment across the transition to middle school. Participants attended 1 of 15 elementary schools when they were in sixth grade and moved into one of three middle schools when they were in seventh grade. These predominantly low-income schools (the average rate of eligibility for free or reduced fee lunch was 66% across the elementary schools and 59% across the middle schools) served nonmetropolitan, small urban communities.

Letters describing the project were given to all students to take home to their parents 2 weeks prior to each data collection. The average mobility rate (average percentage of students who transfer in or out of the school within an academic year) in these schools was high (22% across the elementary schools and 24% across the middle schools), and thus, we maximized the sample size by recruiting new students at each time point. If parents did not want their children to participate in the study, they were instructed to have their child return an attached form to the teacher, to call the school, or to call the researchers at the university number provided on the letter. Fewer than 5% of the parents declined to have their child participate at any time point.

Surveys were administered to students in their classrooms. Instructions and items were read aloud while students read along and responded. Students were told that the purpose of the survey was to find out about students' beliefs and behaviors and that completing it was voluntary. Students were assured that the information in the survey would be kept confidential. We visited the schools on 1 additional day to administer make-ups for students who were absent for survey administration.

### Participants

A total of 738 students participated in the study at Time 1 and had complete information regarding their achievement goals and

achievement. At subsequent time points, we lost some students from our sample (88, 182, and 110, at Times 2, 3, and 4, respectively) and gained some new students (110, 280, and 40, at Times 2, 3, and 4, respectively). Sample instability was due to two factors: school participation and mobility rates. Regarding school participation, we lost some students who went to a nonparticipating middle school and gained some students from nonparticipating elementary schools (in total, three elementary schools and one middle school chose not to participate). After these students were accounted for, the sample instability was comparable with the mobility rates reported by the state for these schools. Because we were examining developmental changes over the middle-school transition, only those students who actually made the transition into middle school (i.e., had data for at least one time point in elementary school and at least one time point in middle school) were included in the analyses. Students who were not African American or European American were dropped because there were too few ( $n = 30$ ) to examine ethnic differences. These restrictions yielded a sample of 588 students (56% girls, 44% boys; 60% African American, 40% European American). There were no significant differences between students in our longitudinal sample and students excluded from our longitudinal sample (i.e., had data at only one of the time points) on achievement goals or achievement at any of the four time points.

### Measures

**Achievement goals.** We used the Patterns of Adaptive Learning Survey (Midgley et al., 1997) to assess achievement goals. *Mastery-approach goal* items (six items) refer to a focus on developing academic competence (e.g., "An important reason I do my work is because I want to improve my skills"). *Mastery-avoidance goals* are not measured in the present study, and thus, mastery-approach goals are referred to as *mastery goals* hereafter. *Performance-approach goal* items (five items) refer to a focus on demonstrating high academic competence relative to other students in the class (e.g., "I like to show my teacher that I'm smarter than the other students in my class"). *Performance-avoidance goal* items (five items) concern a focus on avoiding looking inferior relative to other students in the class ("An important reason I do my work is so that the teacher doesn't think I know less than others"). Goals were found to be reliable in the present sample (see Table 1 for alpha coefficients).

**Achievement.** Students' grades in reading, math, science, English, and social studies were collected from their school records. The grades were coded 1 (*F*) through 13 (*A+*). We computed a GPA for each semester by taking the mean of the five subject grades.

### Handling Missing Data

Hierarchical linear modeling (HLM) is flexible in handling missing data at Level 1, but it cannot handle missing values at Level 2. In the current study, we control for prior GPA and use Time 1 achievement goals to calculate the deviation from Time 1 scores ( $DevT_1$ ). Thus, we had four important Level 2 variables (fifth-grade GPA and three Time 1 achievement goals), and students who joined the study after Time 1 did not have these variables. To include the maximum number of students in the

Table 1  
Means, Standard Errors, and Reliabilities of Achievement Goals and GPA

Time	Mastery goals			Performance-approach goals			Performance-avoidance goals			GPA	
	<i>M</i>	<i>SE</i>	$\alpha$	<i>M</i>	<i>SE</i>	$\alpha$	<i>M</i>	<i>SE</i>	$\alpha$	<i>M</i>	<i>SE</i>
1	3.59	.04	.79	3.34	.04	.75	3.29	.05	.72	7.82	.11
2	3.42	.04	.80	3.00	.05	.78	2.92	.05	.75	7.93	.11
3	3.41	.04	.78	3.04	.05	.80	2.89	.05	.66	6.74	.13
4	3.30	.04	.82	2.95	.05	.82	2.77	.05	.67	6.19	.13

Note. GPA = grade point average. Means are averaged from five data sets through PROC MIANALYZE (SAS, 2003).

analyses, missing values for these Level 2 variables were imputed. A fundamental weakness of single value imputation techniques (e.g., mean substitution, person mean substitution, regression imputation) is the underestimation of standard errors, which affects Type I errors (Allison, 2002; Newman, 2003). To avoid this problem, we employed a multiple imputation (MI) method to fill in the missing data. A strength of MI estimate is the decreased sensitivity to violations of multivariate normality (Allison, 2002). In addition, the MI paradigm neither requires nor assumes that nonresponse is ignorable (Schafer, 1997). MI has been used in HLM contexts (Dearing, Kreider, Simpkins, & Weiss, 2006) to deal with missing predictors at Level 2. In MI, a complete data set is created by filling in a random value for each missing data point. This procedure is repeated to create multiple complete data sets, each of which is subsequently analyzed.

Given that 16% of the participants had one or more missing values, we created five independent data sets to obtain 95% of efficiency (Rubin, 1987, p. 114).<sup>3,4</sup> Then correlations, *t* tests, and HLM analyses were performed on the five imputed datasets. We used PROC MIANALYZE (SAS, 2003) to combine the results from these five data sets and generate valid statistical inference of the parameters. PROC MIANALYZE provides a *t* test, taking into consideration both within- and between-imputation variance.

## Results

### Analyses and Model Specification

The estimated means, standard errors, and reliability coefficients for achievement goals and GPA are provided in Table 1. The presented means are estimated based on the five imputed datasets. Our growth trajectories were fitted to data using PROC MIXED in SAS (Version 9.1; SAS, 2003) with maximum-likelihood estimation.<sup>5</sup> Robust standard errors (which are less biased, even when the random structure of the model is misspecified) were used for testing the fixed effects. All models were simplified until all fixed effects reached significance ( $p < .05$ ). Gender, race, and their interaction terms were tested in preliminary analyses and retained in the final models only when significant. When it yielded a better model fit to data, gender and racial group membership with four categories was used instead of gender or race separately.

### What Is the Nature of the Development of Achievement Goals?

To estimate the general trend of the development of achievement goals across four time points, we estimated three growth-

curve models with each achievement goal as an outcome variable. We estimated the following growth-curve model to examine the general changes in each achievement goal across the four time points:

$$\text{Level 1: Goal}_{ij} = \beta_{0j} + \beta_{1j}(\text{Time})_{ij} + \varepsilon_{ij}$$

$$\text{Level 2: } \beta_{0j} = \gamma_{00} + U_{0j}$$

$$\beta_{1j} = \gamma_{10} + U_{1j},$$

where  $\beta_{0j}$  and  $\beta_{1j}$  are the random intercepts and slopes, respectively, and  $\gamma_{00}$  and  $\gamma_{10}$  are the fixed intercepts and slopes, respectively.

The estimated intercepts, which are the average starting points for the population, were 3.57 for mastery goals (95% confidence interval [CI] = 3.49, 3.64), 3.25 for performance-approach goals (95% CI = 3.17, 3.34), and 3.21 for performance-avoidance goals (95% CI = 3.11, 3.30), respectively. All three types of achievement goals showed a general decline over time, as indicated by the estimated fixed effects of time in each of the three models. Mastery goals declined by  $-.09$  (95% CI =  $-.12$ ,  $-.06$ ). Performance-approach goals declined by  $-.11$  (95% CI =  $-.15$ ,  $-.08$ ). Performance-avoidance goals declined by  $-.16$  (95% CI =  $-.20$ ,  $-.12$ ). There was significant individual variability in both the initial levels and rates of changes of the growth trajectories of all three types of achievement goals, as indicated by the random parts of the three models (see Table 2).

There were substantively meaningful distinctions between each of four time points (between Times 1 and 2, children had one teacher in an elementary-school classroom; between Times 2 and 3, children made the transition to a new middle-school environment; and between Times 3 and 4, children rotated amongst different teachers in middle school). We conducted a series of *t*

<sup>3</sup> We imputed missing values in all variables to do descriptive analyses, *t* tests, and correlations. Level 1 variables do not need to be imputed to conduct HLM.

<sup>4</sup> We ran the analyses with the complete data subset (i.e., the subset of students for whom there were no missing data) without imputing missing values, and the conclusions were identical.

<sup>5</sup> Unstructured variance-covariance matrices for the intercepts and slopes were fit. Various Level 1 error covariance matrices, such as autocorrelated errors, moving average, and autocorrelated moving average were examined in the preliminary analyses, but the inclusion of additional parameters was not warranted by likelihood-ratio test. Thus,  $\sigma^2 I$  (constant and uncorrelated Level 1 error structures) was used for error covariance matrices.

tests to examine changes in goals across different time points (see Table 3 for the results). The results have shown significant mean differences in all three achievement goals between Times 1 and 2 and between Times 3 and 4. There were no significant mean differences in any of the three achievement goals between Times 2 and 3. Thus, declines were more pronounced within, rather than between, school years. Declines within the school year occurred in both elementary and middle school. The declines that occurred between the end of elementary and the beginning of middle school were not significant, indicating that the middle-school transition was not the major contributing source to the overall pattern of decline found for achievement goals during early adolescence.

Next, we examined whether gender and/or race explained variation in students' growth trajectories in achievement goals (see Table 4 for the results). We entered gender and race as Level 2 predictors in the growth-curve models to examine whether the initial levels (i.e., the intercept) and rates of change (i.e., the slope) of achievement goals are a function of these variables. The HLM equation to estimate the gender and racial differences in the changes in achievement goals across the four measurements takes the following form:

$$\text{Level 1: Goal}_{ij} = \beta_{0j} + \beta_{1j}(\text{Time})_{ij} + \epsilon_{ij}$$

$$\text{Level 2: } \beta_{0j} = \gamma_{00} + \gamma_{01}(\text{Gender})_j + \gamma_{02}(\text{Race})_j + \gamma_{03}(\text{Gender} \times \text{Race})_j + U_{0j}$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}(\text{Gender})_j + \gamma_{12}(\text{Race})_j + \gamma_{13}(\text{Gender} \times \text{Race})_j + U_{1j},$$

where  $\text{Gender}_j = 0$  for boys and 1 for girls and  $\text{Race}_j = 0$  for European American and 1 for African American.

### A Mastery Goal

Gender and race were associated with the initial level but not the rate of change in mastery goals. Female students started out with higher levels of mastery goals than did male students. African American students had higher levels of mastery goals than did European American students. The finding that neither gender nor race predicted the slope means that these group differences remained constant across the four time points. The separate main effects of gender and race on the intercept indicated that African American girls were the highest, followed by European American girls, African American boys, and European American boys (all pairwise comparisons were significant). Their level of mastery goals varied, but their growth trajectories moved in parallel fashion across time (see Figure 1).<sup>6</sup>

### A Performance-Approach Goal

Gender and race were associated with both the initial level and the rate of change in performance-approach goals. There was a Gender  $\times$  Race interactive effect on the intercept and a main effect of gender on the rate of change. The results indicated that African American boys had the highest level of performance-approach goals at all time points, compared with all other students. European American boys were similar to all girls initially but had higher

<sup>6</sup> Significant random effects were found in all three goal models. The results indicated that there was significant individual variability in both intercept and slope. However, this is not the focus of the current investigation and, hence, is not discussed.

\* $p < .05$ . \*\* $p < .01$ . \*\*\* $p < .001$ .

levels of performance-approach goals than did all girls later in time (see Figure 2).

#### A Performance-Avoidance Goal

Gender, but not race, predicted the initial levels of performance-avoidance goals. Boys had higher levels of performance-avoidance goals than did girls at Time 1. Neither gender nor race predicted the rate of change in performance-avoidance goals. Thus, the trajectories of performance-avoidance goals for boys and girls are parallel, but the levels of performance-avoidance goals were consistently higher among boys than girls.

#### Does the Association Between Achievement Goals and Achievement Change Across Time?

To address whether achievement goals are predictors of achievement across time, we estimated an unconditional model for GPA to ensure that there was significant random variance in the intercept and slope to proceed with modeling achievement goals as predictors of GPA. The intercept for GPA was 8.08, and the slope was  $-.61$ , indicating that GPA declined over time.

There was significant variability in both the initial level and rate of change over time, as indicated by the random parts of the model:

$$\begin{aligned}\widehat{\text{var}}(U_{0j}) &= 6.33, 95\% \text{ CI } (5.48, 7.18), \text{ and } \widehat{\text{var}}(U_{1j}) \\ &= .53, 95\% \text{ CI } (.42, .64).\end{aligned}$$

The HLM equation to estimate the effects of achievement goals on growth trajectories of achievement takes the following form:

$$\begin{aligned}\text{Level 1: } \text{GPA}_{ij} &= \beta_{0j} + \beta_{1j}(\text{Time})_{ij} + \beta_{2j}(\text{MG})_{ij} + \beta_{3j}(\text{PAP})_{ij} \\ &+ \beta_{4j}(\text{PAV})_{ij} + \beta_{5j}(\text{Time})_{ij}(\text{MG})_{ij} + \beta_{6j}(\text{Time})_{ij}(\text{PAP})_{ij} \\ &+ \beta_{7j}(\text{Time})_{ij}(\text{PAV})_{ij} + \varepsilon_{ij},\end{aligned}$$

where  $(\text{MG})_{ij}$ ,  $(\text{PAP})_{ij}$ ,  $(\text{PAV})_{ij}$  represent goal scores measured at different time points for mastery, performance-approach, and performance-avoidance goals, respectively.

$$\begin{aligned}\text{Level 2: } \beta_{0j} &= \gamma_{00} + \gamma_{01}(\text{Gender})_j + \gamma_{02}(\text{Race})_j + \gamma_{03}(\text{Gender} \\ &\times \text{Race})_j + \gamma_{04}(\text{5th Grade GPA})_j + U_{0j}\end{aligned}$$

$$\begin{aligned}\beta_{1j} &= \gamma_{10} + \gamma_{11}(\text{Gender})_j + \gamma_{12}(\text{Race})_j + \gamma_{13}(\text{Gender} \\ &\times \text{Race})_j + \gamma_{12}(\text{5th Grade GPA})_j + U_{1j}\end{aligned}$$

$$\beta_{2j} = \gamma_{20} + \gamma_{21}(\text{Gender})_j + \gamma_{22}(\text{Race})_j + \gamma_{23}(\text{Gender} \times \text{Race})_j$$

For the remaining  $k = 2$  through 7,

$$\beta_{kj} = \gamma_{k0} + \gamma_{k1}(\text{Gender})_j + \gamma_{k2}(\text{Race})_j + \gamma_{k3}(\text{Gender} \times \text{Race})_j.$$

In contrast to predictors like gender or race, achievement goals do change over time. Thus, in addressing our question about whether the association between achievement goals and achievement change across time, we incorporated achievement goals at Level 1. A changing association can be captured by a significant

Figure 1. Gender and race differences in the development of mastery goals.

interaction between achievement goals and time.<sup>7</sup> We found significant interactions between mastery goals and time and performance-approach goals and time (see Table 5). As recommended by Singer and Willett (2003), we repeated the analyses three more times with time centered at each of the three subsequent time points so we could compare the associations of goals and achievement at different time points. For example, when time is recentered around Time 2,  $\gamma_{20}$  indicates average association between a mastery goal and GPA at Time 2, whereas when time is recentered around Time 3,  $\gamma_{20}$  indicates average association between a mastery goal and GPA at Time 3.

A mastery goal was a significant positive predictor of GPA at all time points except Time 1. The estimates for the mastery goal effect on the levels of GPA were as follows: Time 1,  $\gamma_{20} = .00$  (95% CI =  $-.13, .13$ ),  $t(193) = -.06$ ,  $p = ns$ ; Time 2,  $\gamma_{20} = .13$  (95% CI =  $.02, .24$ ),  $t(45) = 2.33$ ,  $p < .05$ ; Time 3,  $\gamma_{20} = .26$  (95% CI =  $.13, .39$ ),  $t(32) = 4.11$ ,  $p < .001$ ; and Time 4,  $\gamma_{20} = .40$  (95% CI =  $.22, .57$ ),  $t(46) = 4.57$ ,  $p < .0001$ . A performance-approach goal had an initial negative impact that dissipated over time and disappeared once students moved into middle school. The estimates for performance-approach goal effects on the levels of GPA were as follows: Time 1,  $\gamma_{30} = -.19$  (95% CI =  $-.33, -.05$ ),  $t(31) = -2.77$ ,  $p < .01$ ; Time 2,  $\gamma_{30} = -.11$  (95% CI =  $-.23, .01$ ),  $t(17) = -1.94$ ,  $p < .10$ ; Time 3,  $\gamma_{30} = -.02$  (95% CI =  $-.14, .09$ ),  $t(22) = -.43$ ,  $p = ns$ ; and Time 4,  $\gamma_{30} = .06$  (95% CI =  $-.09, .20$ ),  $t(56) = 0.81$ ,  $p = ns$ . A performance-avoidance goal was a significant negative predictor of GPA at all time points. The effect of performance-avoidance goal on the initial level of GPA was  $-.09$  (95% CI =  $-.02, -.16$ ),  $t(223) = 2.43$ ,  $p < .05$ . The direction and magnitude of the effect did not

change over time, as indicated by nonsignificant Performance-Avoidance Goal  $\times$  Time interaction term.

#### *Do Changes in Achievement Goals Have Implications for Changes in Achievement?*

We conducted growth-curve analyses with two different types of predictors of achievement goals to examine the effects of intraindividual changes in achievement goals.<sup>8</sup> In line with procedures outlined by Singer and Willett (2003), we used Time 1 centering to create two achievement-goal predictors, one representing the initial level of goals and one representing gains and losses from the initial level. The initial levels of goals are Level 2 between-individual variables (termed baseline score,  $Time_1 Goal = Goal_{1j}$ ), and deviation scores from the initial levels are Level 1 within-individual predictors of achievement goals (termed  $DevT_1$  scores,  $DevT_1 Goal = Goal_{ij} - Goal_{1j}$ ).  $DevT_1$  scores were computed by subtracting the Time 1 goal scores from goal scores at four time points, and thus, they represent the deviation at each time point from the initial baseline. The significant effects of  $DevT_1$  scores indicate that the students' goal changes from their own initial baseline affect their growth trajectories of GPA. The

<sup>7</sup> Interactions between goals, gender, and race were tested. None of these interactions were significant, and hence, these interaction terms were dropped from the final models.

<sup>8</sup> Analyses with Time 1-centered variables are statistically equivalent with those with raw goal scores (time varying) but enable a different interpretation (see Singer & Willett, 2003, for discussion of this approach).

Figure 2. Gender and race differences in the development of performance-approach goals.

HLM equation that estimates the effects of achievement goals on growth trajectories of achievement with Time 1 centering method takes the following form:

$$\begin{aligned} \text{Level 1: } \text{GPA}_{ij} = & \beta_{0j} + \beta_{1j}(\text{Time})_{ij} + \beta_{2j}(\text{DevT}_1\text{MG})_{ij} \\ & + \beta_{3j}(\text{DevT}_1\text{PAP})_{ij} + \beta_{4j}(\text{DevT}_1\text{PAV})_{ij} \\ & + \beta_{5j}(\text{Time})_{ij}(\text{DevT}_1\text{MG})_{ij} + \beta_{6j}(\text{Time})_{ij}(\text{DevT}_1\text{PAP})_{ij} \end{aligned}$$

$$+ \beta_{7j}(\text{Time})_{ij}(\text{DevT}_1\text{PAV})_{ij} + \epsilon_{ij},$$

where  $(\text{DevT}_1\text{MG})_{ij}$ ,  $(\text{DevT}_1\text{PAP})_{ij}$ , and  $(\text{DevT}_1\text{PAV})_{ij}$ , represent deviation scores from Time 1 scores for mastery, performance-approach, and performance-avoidance goals, respectively.

$$\text{Level 2: } \beta_{0j} = \gamma_{00} + \gamma_{01}(\text{Gender})_j + \gamma_{02}(\text{Race})_j + \gamma_{03}(\text{Gender})_j$$

Table 5  
The Association Between Achievement Goals and GPA at Time 1

Model for linear change				
M change rate	-1.33 (-1.62, -1.05)	.15	573	-9.19***
Model for time by time-varying predictors				
Time × Mastery Goals	0.13 (.07, .20)	.04	396	3.82***
Time × Performance-Approach Goals	0.08 (.02, .14)	.03	824	2.75**

Note. GPA = grade point average. The omitted category is African Americans. Estimates for European Americans are shown in the table. *dfs* are from PROC MIANALYZE (SAS, 2003), not from hierarchical linear modeling.

\*  $p < .05$ . \*\*  $p < .01$ . \*\*\*  $p < .001$ .

$$\begin{aligned} & \times \text{Race})_j + \gamma_{04}(\text{Grade5 GPA})_j + \gamma_{05}(\text{Time}_1\text{MG})_j \\ & + \gamma_{06}(\text{Time}_1\text{PAP})_j + \gamma_{07}(\text{Time}_1\text{PAV}) + U_{0j} \\ \beta_{1j} = & \gamma_{10} + \gamma_{11}(\text{Gender})_j + \gamma_{12}(\text{Race})_j + \gamma_{13}(\text{Gender} \\ & \times \text{Race})_j + \gamma_{14}(\text{Time}_1\text{MG})_j + \gamma_{15}(\text{Time}_1\text{PAP})_j \\ & + \gamma_{16}(\text{Time}_1\text{PAV})_j + U_{1j} \end{aligned}$$

For the remaining  $k = 2$  through 7,  $\beta_{kj} = \gamma_{k0}$ , where  $(\text{Time}_1\text{MG})_j$ ,  $(\text{Time}_1\text{PAP})_j$ , and  $(\text{Time}_1\text{PAV})_j$  represent Time 1 scores for mastery, performance-approach, and performance-avoidance goals, respectively.

Because of the inclusion of the time varying predictors at Level 1, the intercept ( $\gamma_{00}$ ) and the slope parameter ( $\gamma_{10}$ ) represent the average initial level and the rate of change after adjusting for fifth-grade GPA, gender and racial differences, and goal effects. If both the main effects of goals (i.e.,  $\gamma_{20}$ ,  $\gamma_{30}$ ,  $\gamma_{40}$ ) and the Goal  $\times$  Time interaction terms (i.e.,  $\gamma_{50}$ ,  $\gamma_{60}$ ,  $\gamma_{70}$ ) are significant, the results would indicate that achievement goals predict both the initial levels and the rates of changes. If only the main effect term of a goal is significant, then the goal affects the level of growth trajectory and the effects are constant over time. If the main effect of goal and the effect of interaction term are in different signs, then the results indicate that the effects of goal undergo qualitative change over time. Insignificant terms are dropped so that final models include only significant fixed effects at the .05 level. The results are shown in Table 6.

### Predicting GPA

**Mastery goals.** Baseline mastery goal scores did not predict the initial levels; however, they positively influenced the rates of

change in GPA over time. Thus, students who initially had high mastery goal scores showed more desirable patterns of changes in GPA over time. In addition, the  $\text{Dev}T_1$  positively predicted the growth trajectories of GPA. Thus, gains from the initial baseline score of mastery goals yielded additional benefits in terms of rate of change in GPA.

**Performance-approach goals.** Baseline performance-approach goal scores predicted neither the levels nor the rates of changes; however, the  $\text{Dev}T_1$  performance-approach goal scores had a negative effect on the intercept but a positive effect on the slope. Thus, inclines or declines from the baseline affected the developmental trajectories of GPA, but as we found in the previous analysis, the effect varied over time. That is, students who showed increases in performance-approach goals from their initial baseline showed more adaptive patterns of changes in GPA, but because of the negative effect on the initial level of GPA, the positive effect on the slope did not compensate for the initial negative effect.

**Performance-avoidance goals.** Baseline performance-avoidance goal scores predicted initial levels but not the rate of change of GPA. The results indicate that baseline performance-avoidance goals predicted consistently lower levels of GPA across all time points. Gains from the initial baseline lowered the levels of GPA even more, as indicated by the significant effects of  $\text{Dev}T_1$  performance-avoidance goal scores on the initial levels of GPA. Taken together, the results supported the conclusion that performance-avoidance goals were associated with consistently lower levels of GPA.

### Supplemental Analyses to Address Causality

In the current study, we examined whether achievement goals predict achievement. The temporal sequence of our design (our

measurements of achievement goals are at the beginning of the semester, and GPA represents achievement across the entire semester), as well as controlling for prior achievement, helped address reciprocal causation concerns but did not preclude the possibility that achievement influences subsequent achievement goals. Thus, we conducted HLM analyses to estimate the effect of prior achievement on growth trajectories of achievement goals (see Table 7 for the results). Previous semester GPA from spring of fifth grade to fall of seventh grade were entered as a time-varying predictor for growth trajectories of achievement goals from fall of sixth grade to spring of seventh grade. Prior achievement level did not predict the growth trajectories of mastery goals. Prior achievement level predicted the levels but not the rates of change in the growth trajectories of performance-approach goals and avoidance goals. These results indicated that roughly a one-letter-grade difference in GPA yielded a one-point drop in performance-approach and avoidance goals in the following semesters. Students who did well in the previous semester were less likely to endorse either performance-approach or avoidance goals. These relationships between prior achievement and subsequent goal adoption did not change over time, as indicated by nonsignificant Goal  $\times$  Time interaction. Results are provided in Table 7.

### Discussion

Motivation, learning, and achievement are not static. However, most of the research on a prominent motivational construct, the achievement goal, has considered measurements of goals at only one or two time points. Thus, the research design and analytic methods have not captured the changing nature of achievement

goals. With a longitudinal design and growth-curve analytic techniques that incorporated both measurements of achievement goals and achievement across time, the present study expanded current understanding of the nature and consequences of achievement goals. Our developmental approach provided important insights into the development of achievement goals, the association of achievement goals with achievement across time, and the consequences of changes in achievement goals for achievement.

### The Development of Achievement Goals

Consistent with prior research reporting maladaptive changes in motivation, engagement, and achievement during early adolescence (Eccles et al., 1997), achievement goals were found to decline in general, regardless of the type. Previous longitudinal research has assessed achievement goals at only two points in time and in different grades. With four measurements of achievement goals (fall and spring of sixth grade and fall and spring of seventh grade), we were able to distinguish within-school-year from between-school-year changes. The general pattern across these four time points was a decline from fall to spring in sixth grade, stability from spring of sixth grade to fall of seventh grade, and a decline from fall of seventh grade to spring of seventh grade. Previous research has implicated the transition to middle school as the source of the decline in goals (E. M. Anderman & Midgley, 1997; L. H. Anderman & Anderman, 1999). However, with more time points, we found that the major source of the overall decline was within year, not between years. The average level of achievement goals in the beginning of middle school was similar to that in the spring of elementary school, which suggests that moving into

\*\*\**p* < .001.

a new, larger school environment was not immediately a catalyst for dramatic shifts in level of goals.

A study concerning the change in elementary-school students' achievement goals for different types of literary tasks found declines from fall to spring (Meece & Miller, 2001). Thus, the dissipation of goals in a similar classroom setting may be a trend that is in place prior to middle school. The finding that declines in goals occur with more experience in a specific classroom merits more attention. What aspects of the classroom environment are contributing to this? Does novelty, or an element of the unknown, heighten the pursuit of goals? Much attention has been devoted to classroom features that are associated with student goal pursuit, but researchers generally focus on between-class differences of data at one time point (Wigfield et al., 2006). Future research that examines how classroom features are related to the development of goals within the same environment could provide important insights into how teachers might best support students' goals.

For mastery and performance-avoidance goals, the developmental pattern was the same for all groups. However, for performance-approach goals, gender and race were important in understanding the developmental patterns (see Figure 3). For girls, performance-approach goals showed a similar pattern to that of the other goals (within-year declines for both elementary- and middle-school years). For boys, performance-approach goals declined during elementary school but increased during middle school. Considered in tandem with a Gender  $\times$  Race interaction on the intercept, the results indicated that African American boys had the highest level of performance-approach goals of all students, at all time points, whereas European American boys were similar to girls in elementary school but had higher levels of performance-approach goals than did girls by the end of the first year in middle school. It is interesting that boys' performance-approach goals increase after

moving into a context that is typically described as more competitive and performance oriented (Eccles et al., 1997; Midgley, 1993). In general, boys' social interactions with peers involve more competition and dominance seeking than do girls' (e.g., Hartup, 1989; Maccoby, 1990; Rose & Rudolph, 2006). Perhaps there is a match between this gendered characteristic and the middle-school context that causes performance-approach goals to increase for boys and not girls. Being better than others in the classroom may become more important to boys during early adolescence because it is in line with societal ideals of masculinity that emphasize competition, winning, and dominance. These issues may be salient for African American boys even earlier, as they had higher performance-approach goals than all other students, even before the increase for boys that occurred in middle school. It is concerning that African American boys had higher performance-approach goals than did all other students in elementary school, given that performance-approach goals had a deleterious impact on achievement in that setting.

Although the developmental patterns for mastery and performance-avoidance goals were the same for all groups, there were gender and race differences in the levels across time. Consistent with prior research, girls and African American students were higher in mastery goals. Also consistent with prior research, boys were higher in a performance-avoidance goal than were girls. However, there were no interactive effects of either gender or race with goals on achievement, which indicated that the relation of goals to achievement was the same for all groups across time. Thus, similar to other aspects of motivation (e.g., ability perceptions), the mean levels may vary, but the nature of the consequences do not (see Graham, 1994, for a review). Future research could further our understanding of group differences by examining if the antecedents of achievement goals are similar for all students.

Figure 3. Gender differences in the development of performance-avoidance goals.

It may be that gender and/or ethnicity play a role in students' perceptions of or experiences in classrooms that may explain the different levels of achievement goals.

### *The Changing Association of Achievement Goals and Achievement Across Time*

By treating achievement goals as time-varying predictors of achievement across time, we were able to examine whether the associations of achievement goals to achievement change during early adolescence. Our sample made a transition into middle school during this time, which allowed us to examine these associations across contexts that vary in terms of emphasis on competition and social comparison (see Eccles et al., 1997; Juvonen et al., 2004; Midgley, 1993). When we controlled for prior achievement, a performance-avoidance goal had a consistent negative association with subsequent achievement across the four time points, which is in line with prior research that consistently documents the negative consequences of such goals. When we controlled for prior achievement, mastery goals were positive predictors of subsequent achievement at Times 2–4. Thus, mastery goals fostered the achievement of young adolescents, especially in the middle-school context. Findings for a performance-approach goal captured changing associations across time. A performance-approach goal was detrimental to achievement in the elementary-school context, particularly at Time 1 (negative association was significant at Time 1 and marginally significant at Time 2) and then became unrelated to achievement when students moved into middle school.

It has been suggested that as students advance through the educational system, the context becomes more competitive, and the consequences of achievement goals may change; a performance-approach goal may become more adaptive, and a mastery goal may become less adaptive for achievement (Midgley et al., 2001). The findings for a performance-approach goal were somewhat in line with this idea, as the detrimental effects on achievement dissipated as students moved into middle school. The findings for a mastery goal were contrary to this idea, as mastery goals became increasingly positive predictors of achievement as students moved into middle school. One possibility is that a mastery goal is especially facilitative of achievement in challenging academic situations. Grant and Dweck (2003) found that a mastery goal predicted more adaptive coping and higher achievement in the face of challenge for undergraduate students enrolled in a difficult premedical course. Students in our sample navigated a transition from a small elementary school to a large middle school. Against this backdrop, we saw GPA decline from elementary school to middle school. Thus, students likely experienced academic challenge or uncertainty during this transition. Our data indicate that a mastery goal supported students' achievement during this transition. However, a mastery goal was a positive predictor of achievement in the spring of elementary school, so this would not be a complete explanation.

The pattern of results for achievement goals and achievement are in sharp contrast to those consistently found for college students. For college students, the relationship between achievement goals and achievement is consistently null for a mastery goal and positive for a performance-approach goal (see Harackiewicz, Barron, Pintrich, et al., 2002, for a review). However, our findings are

in line with much research on younger samples (e.g., Kaplan & Maehr, 1999; Pajares & Valiante, 2001; A. M. Ryan et al., 2005; Wentzel, 1993). Thus, conclusions about which achievement goals are best for learning and achievement are different for younger students in school and older adolescents in college. In addition to the educational climate becoming more competitive as students progress through the system, there are numerous other differences in context, sample, and developmental stage that may contribute to an explanation of the different patterns. Young adolescent students learn among their peers in classes all day, in contrast with college students who direct their own learning for much of the day. Young adolescent students have frequent assignments and feedback on their learning, whereas college students may only have two or three papers or exams per semester. Younger samples in public schools represent heterogeneity of ability levels from the broad spectrum of society, whereas samples taken from college represent only the upper ability levels. All of these differences may contribute to an explanation of why mastery goals are important to the achievement of young adolescents but not to college students.

The implication of our research is that a mastery goal should be encouraged in early adolescent students because it supports learning and achievement. In recent years (and primarily on the basis of research on college students), mastery goals have been lauded as beneficial for supporting intrinsic motivation but not achievement (e.g., Harackiewicz, Barron, Pintrich, et al., 2002; Harackiewicz & Tauer, 2006). However, achievement is often the main concern of administrators and educators, especially given the current climate of standardized testing brought on by the No Child Left Behind Act of 2001 (2002). If mastery goals are not seen as having benefits for achievement, it is unlikely they will garner much attention for school reform. This could represent a missed opportunity for children in our schools, as much work has been done regarding how to create an educational climate that encourages mastery goals (e.g., Ames, 1992; Maehr & Midgley, 1996). Thus, it is critical to take a developmental perspective and distinguish patterns for younger students from patterns found for college students regarding achievement goals and achievement.

### *The Implications of Changes in Achievement Goals for Changes in Achievement*

The benefits of mastery goals for achievement were also seen in our third set of analyses, in which we used a within-individual approach to assess the development of students' achievement goals. Our first two sets of analyses concerned general patterns and variations between students (the first pertaining to the development of goals and the second pertaining to the associations of goals to achievement across time). Although general patterns are important in understanding normative shifts that occur, they do not address the significant variability in these patterns that exists for individual students. Regarding the development of goals, not all students conform to the general declining pattern of achievement goals. Regarding the changing goals–achievement relationship, there are intraindividual differences that tell us something different about the motivation–achievement link than do the interindividual differences. Similar to most prior research, our examination of general patterns of the link between achievement goals and achievement across time concerned how high or low scores in different types of goals, compared with other students, explained

subsequent variations in achievement. In our final set of analyses, we focused on within-individual change to determine if inclines or declines from student's initial level of goals were important to understanding students' personal trajectory of achievement. Focusing on intraindividual change captures the dynamic nature of achievement goals that is widely acknowledged in theory but seldom captured in analytic approaches.

Fluctuations in mastery and performance-approach goals within individual students were important for a thorough understanding of the effects of achievement goals. In particular, deviation scores provided insight into how a mastery goal promotes positive changes in achievement across time. Above and beyond baseline scores, changes in mastery goals promoted changes in achievement. When we controlled for initial level, students who increased their mastery goals exhibited greater gains in achievement across time. Documenting such effects has important educational implications because it indicates that even for students with a "maladaptive" goal profile (i.e., low mastery goals), teachers only need to move them in the right direction for students to reap some achievement benefits. Encouraging a student to intensify his or her mastery goal may help students actually master the material. Personal reminders from teachers about the importance of a mastery goal may sustain or boost students' focus on mastery goals throughout the year, and such positive developments will, in turn, sustain or improve their achievement over time.

### *Prior Achievement as a Predictor of Achievement Goals*

Our supplemental analyses indicated that prior achievement was not related to subsequent mastery goals and was negatively related to performance goals (both approach and avoidance). When students' grades increased, their performance goals were more likely to go down. These findings are not what one would expect on the basis of prior theory and research indicating that high perceptions of competence lead to approach goals and low perceptions of competence lead to avoidance goals (Elliot, 2005). Because perceived competence and academic performance are moderately to highly correlated, one would expect a similar pattern for GPA. However, the nature of our design and analyses make them hard to directly compare with previous research. We controlled for prior achievement and modeled intraindividual changes in GPA. Thus, we examined the effects of changes in GPA, controlling for prior levels, on changes in achievement goals. With this approach, we documented that changes in achievement were important for performance goals and not for mastery goals. Our results suggest that changes in achievement may affect students' adoption of mastery versus performance goals, rather than approach versus avoidance goals.

It is encouraging that prior achievement is not important to mastery-goal pursuit, as it suggests that low achievers may be just as amenable to intervention as high achievers. We know a great deal about teacher behaviors that are important to students' goals. Ames (1990, 1992) has described how teacher practices in six categories (Task, Authority, Recognition, Grouping, Evaluation, Time) can promote a mastery-goal emphasis in classrooms. Qualitative work has expanded on Ames's work and noted how affect and teacher-student relationships are also critical to fostering a mastery-oriented climate (Patrick, Anderman, Ryan, Edelin, & Midgley, 2001; Patrick, Turner,

Meyer, & Midgley, 2003; Turner et al., 2002). Linnenbrink (2005) designed an intervention based on feedback to small groups that was successful in increasing students' mastery goals. Blackwell, Trzesniewski, and Dweck (2007) designed a Web-based intervention that increased students' malleable theory of intelligence, which in turn increased students' mastery goals and grades. Thus, although there are challenges in the current educational climate (see Urdu & Turner, 2005), there is much knowledge about how to encourage mastery goals in students. All of this research could be drawn on to promote mastery goals in early adolescent students and to best support their learning and achievement.

### *Limitations and Future Research*

Although our developmental approach provided new insights regarding achievement goals, there are several limitations that need to be considered and possibly addressed in future research. First, our sample only represented two ethnic groups, and it is therefore not known whether the results would generalize to other ethnic groups. Second, we only examined grades as indicators of achievement. This was appropriate given our focus on within-year and between-year development of goals and achievement. Nonetheless, standardized tests provide different information about students' learning and achievement than do grades, and future work that examines the link between achievement goals and standardized tests across time could broaden our understanding of the implications of goals for achievement (see K. Ryan & Ryan, 2005; K. Ryan, Ryan, Arbutnot, & Samuels, 2007, for a discussion of achievement goals and standardized-test performance).

Third, a longer time frame would have provided additional understanding of the development of achievement goals. With our four time points of data, we documented within-year, but not between-year, declines in achievement goals in both sixth and seventh grades, indicating that the transition did not immediately have an impact on the average level of goals. However, it may be that the typical yearly pattern for students' goals is to decline across the year and then recover over the summer break, beginning high again the following year. It is possible that the middle-school transition does have an impact on the average level of student goal pursuit by disrupting this cycle. Future research encompassing additional years before the transition could further our understanding of typical cycles of motivation. In a cross-sectional study, Pajares and Cheong (2003) found nonlinear changes in mastery goals and performance-approach goals (decrease from elementary school to middle school and increase in high school for mastery goals and decrease from elementary school to middle school and no change in high school for performance-approach goals). There was no change in performance-avoidance goals. This is another intriguing developmental pattern that could be further investigated with longitudinal data. Although practically challenging, longitudinal studies following students from elementary school to college could better examine the proposition that performance-approach goals exert a positive effect on achievement and mastery goals become null as students advance through the educational system.

Fourth, we asked students about their achievement goals for schoolwork in general, and our results may not generalize across

all subjects. Recent research on achievement goals has investigated students' general goals as well as subject-specific goals.<sup>9</sup> Both approaches are valid because achievement goals are conceptualized as a function of individual differences (i.e., personality, dispositions, or general motives) as well as due to features of the immediate environment. Students tend to approach schoolwork in different subjects in a similar way, as indicated by moderate to large correlations between the goals in different subjects (Bong, 2001; Elliot & McGregor, 2001). Further, achievement goals operate similarly across different academic subject areas (Bong, 2001; Wolters et al., 1996), so measuring at a general level is unlikely to confound results. Nonetheless, there are differences in the nature of knowledge and teaching between subjects that may contribute to different developmental patterns at the subject-specific level, and this could be a fruitful area for future research.

## Conclusion

By taking advantage of current advances in growth-curve analytic techniques, we were able to garner a more complete understanding of students' achievement goals and the importance of these goals for achievement. Our focus on the development of goals across time in early adolescence revealed important patterns for this age group. At this stage of life, goals exhibit within-year rather than between-year decreases (with the exception of boys' performance-approach goals, which increase in middle school). As students move through early adolescence, mastery goals become increasingly beneficial for achievement. Performance-approach goals are detrimental in elementary school and provide no benefits in middle school. Performance-avoidance goals consistently undermine achievement throughout early adolescence. Personal increases in mastery goals over time provide a boost to student achievement. The overall implications of the present research is that mastery goals should be supported and encouraged in early adolescent students to best support their achievement. This recommendation is a deviation from recent conclusions based on data from college students regarding achievement goals and achievement. Thus, results highlight that a developmental perspective is critical to understanding achievement goals and achievement. More generally, we hope the results highlight the contribution a developmental approach can make toward understanding motivation and achievement. It is only with a complete understanding of the development of motivation, engagement, and achievement in school that we can make recommendations to educators and parents about what matters for student learning.

<sup>9</sup> Our review of articles concerning achievement goals in the last 5 years of the *Journal of Educational Psychology* indicated that about half of the research measured goals at the general level and about half measured goals specific to a certain subject or class.

# An Exploration of Young Adolescents' Social Achievement Goals and Social Adjustment in Middle School

Allison M. Ryan  
University of Illinois

S. Serena Shim  
Northern Arizona University

Two studies investigated the proposition that social achievement goals (different orientations toward social competence) are an important aspect of young adolescents' social motivation. Study 1 ( $N = 153$  6th-grade students) established that different orientations toward developing or demonstrating social competence can be seen in young adolescents' responses to open-ended questions about their social goals and social competence. Study 2 ( $N = 217$  6th-grade students) evaluated a new survey measure of social achievement goals for young adolescents. Exploratory factor analyses indicated a 3-factor model (social development, demonstration-approach, and demonstration-avoid goals). Different social achievement goals were associated with distinct patterns of subsequent self- and teacher-reported social adjustment (prosocial, aggressive, and anxious solitary behaviors, as well as social worry, best-friend quality, and perceived popularity). Effects for social achievement goals were independent of perceived social competence and gender.

**Keywords:** motivation, peers, social adjustment

A common portrayal of young adolescents is that this is an age group desperate for peer approval. But is it only validation from peers as being "cool" or "popular" that makes an adolescent feel socially competent? Do adolescents have an inner compass for evaluating themselves, one of personal standards gleaned from their past successes and failures and oriented toward the outcome of developing positive peer relationships? Can such an inner compass be nurtured and guide young adolescents more smoothly toward adjustment in middle school? Different orientations to competence (demonstrating vs. developing competence) have been examined extensively in the academic, athletic, and work domains. However, little is known about such orientations in the social domain, and existing work has focused on adults (Elliot, Gable, & Mapes, 2006; Horst, Finney, & Barron, 2007; Ryan & Shim, 2006; but see also Erdley, Cain, Loomis, Dumas-Hines, & Dweck, 1997). Different orientations toward achieving competence are the crux of an achievement goal approach to motivation. This approach has proven to be powerful in explaining processes and outcomes for adolescents in the academic and athletic domains (Elliot & Dweck, 2005). We propose that social achievement goals are relevant to young adolescents' social strivings with peers and will advance understanding of their social adjustment in middle school.

Social adjustment in middle school is a source of increasing concern for educators, parents, and researchers. A recent review of 20 years of research, including international comparisons, depicts

middle schools in the United States as the Bermuda Triangle of education (Juvonen, Le, Kaganoff, Augustine, & Constant, 2004). Early adolescence marks the beginning of a downward trend in academic and social adjustment for many children. U.S. middle school students have the highest rate of emotional problems and most negative views of peer culture among the 11 countries included in the report (Juvonen et al., 2004). Attention to social adjustment in middle school is important in its own right, but as social and academic adjustment are interdependent, it is also critical for realization of recent academic benchmarks for this age group (e.g., No Child Left Behind mandates). Promoting positive outcomes for young adolescents, such as prosocial behavior and positive peer relationships, and diminishing negative outcomes, such as aggressive behavior and social anxiety, are critical issues facing educators. Key to finding solutions is elucidating the factors that underlie social adjustment in middle school.

## An Achievement Goal Approach

To understand social adjustment in middle school, we take an achievement goal approach, which is different from the more typical content approach to social goals. A content approach is concerned with what outcomes individuals pursue and identifies categories of goals that characterize what individuals want (Grant & Dweck, 2003; Pintrich, 2000; Wentzel, 2000). Research has been informative in documenting the various goals that children and adolescents strive for in social situations and has highlighted that individuals often have goals for affiliation, responsibility, nurturance, and intimacy (e.g., Ford, 1992; Wentzel, 2001). On the lighter side, individuals often want companionship or fun (e.g., Anderman, 1999; Jarvinen & Nicholls, 1996; Wentzel, 2001). On the darker side, individuals may desire revenge, domination, or control over others (e.g., Chung & Asher, 1996; Erdley & Asher, 1996; McAdams, 1987; Ojanen, Gronroos, & Salmivalli, 2005; Rose & Asher, 1999). Achievement goals transcend various con-

tent or outcome goals that are salient to individuals in social settings (Grant & Dweck, 2003; Pintrich, 2000; Wentzel, 2000) and capture key distinctions in orientations to competence (Dweck, 1986; Elliot, 2005). Regardless of whether people want intimacy or fun or both in a social situation, it is likely they also want to feel socially competent. Whether they are oriented to demonstrate their social competence, develop their social competence, or possibly to do both has implications for their beliefs and behavior. An achievement goal approach does not compete with a content approach, but instead provides a new angle, and thus it will complement and expand current understanding of young adolescents' social motivation and adjustment. Because the present research builds on a theoretical framework rooted in the academic domain, it will be informative about general motivational processes that promote or hinder adaptation across domains.

In the present research we expand Ryan and Shim's (2006) conceptualization of social achievement goals (social development, social demonstration-approach, and social demonstration-avoid) to young adolescents. We examine three achievement goals that are analogous to those identified in other domains, although described with different terms (e.g., "mastery" and "performance" in the academic domain, see Elliot & McGregor, 2001; and "task" and "ego" in the sports domain, see Duda & Nicholls, 1992). A *social development goal* is concerned with developing social competence with peers. The focus is on learning new things, growth, and improvement. Success is judged by whether one is improving social skills, deepening the quality of relationships, or developing social life in general. A *social demonstration-approach goal* focuses on demonstrating social competence and gaining from peers positive judgments that one is socially desirable. A *social demonstration-avoid goal* is concerned with demonstrating that one does not lack social competence. The focus is on avoiding doing something that would incur negative judgments from peers and indicate social undesirability. With both social demonstration goals, attention focuses on the appearance of the self, especially in relation to others. For a social demonstration-approach goal, success is garnering positive feedback from peers, attaining social prestige, and having a good reputation compared to others (e.g., being popular or seen as important); for a social demonstration-avoid goal, success is avoiding negative judgments from peers compared to others and lacking a reputation as socially awkward or ineffective (e.g., not being seen as a "loser" or "geek"). Similar to the distinction made for demonstration goals, there has been some attention to bifurcating development goals into separate approach and avoid goals, although Ryan and Shim did not include this in their conceptualization of achievement goals in the social domain (neither did Horst et al., 2007, nor Elliot et al., 2006). Such development-avoid goals have been viewed as less prevalent in real-world situations and have weaker relations with adjustment variables in the academic domain (Elliot, 2005). Given the weaker conceptual and practical justifications for a development-avoid goal, we do not include it in our first investigation of social achievement goals in young adolescents.

### Overview of Present Research

The overarching goal of the present research is to examine whether social achievement goals are an important aspect of social motivation for young adolescents and have implications for their

social adjustment in school. Study 1 is a pilot study in which we examine whether social achievement goals are relevant for young adolescents' social motivation by collecting open-ended data about their descriptions of social goals and social competence. This is an important first step because, unlike most experiments or surveys, this can illustrate that different orientations toward social competence can be seen when young adolescents describe their social goals in their own life, in their own words. In Study 2, informed by Study 1, we create new survey items to assess young adolescents' social achievement goals. We explore the structure and nature of social achievement goals and investigate their implications for key aspects of social adjustment in middle school (prosocial behavior, overt aggressive behavior, anxious solitary behavior, social worry, positive features within close friendships, and perceived popularity). Recent research has examined social achievement goals in adults and found that they are distinct factors that differentially relate to self-reports of psychological well-being (Elliot et al., 2006; Horst et al., 2007; Ryan & Shim, 2006). However, we do not know if social achievement goals are an important aspect of social motivation for young adolescents and have implications for their social adjustment in school. In the following sections, we further describe social achievement goals, their likely relevance during early adolescence, and our hypotheses about their significance for social adjustment during middle school.

### A Social Development Goal During Early Adolescence

With its focus on improving social competence, a social development goal is expected to relate to adaptive beliefs and behaviors. The nature of peer relationships evolves markedly during early adolescence, and it is likely that a social development goal would be adaptive in successfully navigating the changing terrain of peer relationships during early adolescence. Just as thinking skills advance (Keating, 2004), conceptions of peer relationships, interpersonal understanding, and communication become more sophisticated during early adolescence (Eisenberg & Morris, 2004; Ford, 1982; Selman, 1980; Youniss & Smollar, 1985). Friendships are increasingly characterized by higher levels of empathy, self-disclosure, and responsiveness to others' thoughts and feelings (Newcomb & Bagwell, 1995; Savin-Williams & Berndt, 1990). In addition, many children make a transition to middle school that disrupts friendships and thrusts young adolescents into a much larger peer network (Eccles, 2004). A focus on developing peer relationships is likely to promote reflection on the evolving criteria of friendships during early adolescence and promote successful peer relationships.

As an approach goal (i.e., focusing on a positive outcome), a social development goal is likely to be undergirded by positive views of one's social competence and enhanced efficacy to achieve desired social outcomes (as found in other domains—see Elliot, 2005, for a review; and as found with adults in the social domain—see Ryan & Shim, 2006). Many social situations are likely to offer opportunities for developing social skills and friendships, and thus social development goals are likely to foster prosocial behavior and diminish aggressive behavior with peers. The quality of peer relationships is also likely to be enhanced. To achieve the goal of developing positive relationships, adolescents are more likely to attend to cues regarding compatibility with others, reflect on what is best for the relationship, and remember

information about their peers. These hypotheses are supported by research with adults that found a social development goal is related to positive perceptions of social relationships (Elliot et al., 2006; Horst et al., 2007; Ryan & Shim, 2006).<sup>1</sup> These hypotheses are also supported by research in the academic domain that has linked a mastery goal (analogous to a development goal in the social domain) to enhanced efficacy, preference for challenging and novel work, deep processing strategies, information retention, adaptive help seeking, and general engagement (see Elliot, 2005, for a review).

### Social Demonstration Goals During Early Adolescence

During adolescence, peer relationships also change regarding social comparison behavior and self-conscious emotions, which is relevant for social demonstration goals. In the context of school, students spend their time among peers and have much opportunity to observe and evaluate characteristics of their peers in a variety of situations. By early adolescence, students use social comparative information to evaluate their competence (Ruble, Boggianno, Feldman, & Loeb, 1980). Cognitive development also affords more adept perspective-taking abilities (Selman, 1980), which often results in young adolescents' unsettling realization that they are the focus of others' attention (termed the "imaginary audience"; Elkind, 1967). Compared to preadolescents and older adolescents, younger adolescents are more self-conscious (Simmons, Rosenberg, & Rosenberg, 1973). Simultaneously, during early adolescence students are increasingly focused on the emerging social phenomenon of popularity (high prestige and visibility among students at school; Eder, 1985; LaFontana & Cillessen, 2002; O'Brien & Bierman, 1988). Thus, given the increasing attention to comparisons and judgments of social attributes, it is likely that social demonstration goals are salient to many young adolescents.

### Social Demonstration-Approach Goal

A social demonstration-approach goal is conceptualized to be a more complex goal serving both approach tendencies (striving to achieve success, undergirded by high perceived social competence) and avoidance tendencies (concern with others' judgments and thus also undergirded by fear of failure; see Elliot & Church, 1997, for evidence in academic domain). Given the inherent approach nature of a social demonstration-approach goal, it will be positively associated with approaching and engaging in social situations with peers. Students who strive to achieve socially because they desire social status or recognition are likely to feel socially competent and interact with peers to achieve their goal (Ryan & Shim, 2006). However, the goal of demonstrating social superiority is likely to lead to aggression as well as prosocial behavior. Research has found that aggressive behavior is associated with achieving cool or popular status among peers (LaFontana & Cillessen, 2002; Parkhurst & Hopmeyer, 1998; Rodkin, Farmer, Pearl, & Van Acker, 2000; Rose, Swenson, & Waller, 2004).<sup>2</sup> Students who are perceived as popular by their peers also exhibit prosocial behavior, suggesting that a combination of aggressive and prosocial behaviors is effective in garnering social status (Hawley, 2003). These hypotheses are supported by research in the academic domain that has linked a performance-approach goal

(analogous to a social demonstration-approach goal) to engagement as well as disruptive behavior in the classroom (Kaplan, Gheen, & Midgley, 2002).

### Social Demonstration-Avoid Goal

With its focus on avoiding negative judgments, a social demonstration-avoid goal is expected to lead to maladaptive beliefs and behaviors. As an avoidance goal, it is expected to be undergirded by negative views of one's social competence and thus associated with diminished efficacy to achieve desired social outcomes (as found in other domains—see Elliot, 2005, for a review; and as found with adults in the social domain—see Ryan & Shim, 2006). Avoidance or withdrawal from social situations is likely to be preferred to engaging in social interactions, as it is safer and satisfies the goal of avoiding possible negative outcomes. Congruent with the focus on negative possibilities, a social demonstration-avoid goal is associated with social anxiety. The quality of peer relationships also suffers because a focus on negative outcomes and being overly self-conscious and afraid of failure is likely to undermine positive interactions with peers by increasing anxious or avoidant strategies and behaviors. Thus, a social demonstration-avoid goal is expected to hinder the formation of positive peer relationships. These hypotheses are supported by research with adults that links a social demonstration-avoid goal to negative perceptions of social relationships (Horst et al., 2007; Ryan & Shim, 2006), higher social worry (Ryan & Shim, 2006), increased fear of negative evaluation (Horst et al., 2007), and loneliness (Elliot et al., 2006). This is also in line with findings that negative approval-based self-appraisals are associated with increased social anxiety (Rudolph, Caldwell, & Conley, 2005). These hypotheses are also supported by research that has linked an academic performance-avoid goal (analogous to our social demonstration-avoid goal) to avoidant behavior and anxiety in academic situations (Middleton & Midgley, 1997; Ryan, Patrick, & Shim, 2005; Skaalvik, 1997).

### The Role of Perceived Social Competence

An additional aim of our research is to examine the role of perceived social competence in regard to social achievement goals and social adjustment. Perceived social competence refers to student beliefs about how good their skills and abilities are in the social domain (Harter, 1982). As we have described in our conceptualization, we expect a positive correlation between perceived social competence and both approach goals (social development

<sup>1</sup> Elliot et al. (2006) investigated "friendship-approach" and "friendship-avoid" goals that are conceptually similar to social development and social demonstration-avoid goals, but whose items focus specifically on friends and close relationships.

<sup>2</sup> Researchers have measured "popular" in different ways. One way is to ask children to list whom they like and whom they dislike in a classroom (referred to as sociometric status). Children with many like and few dislike nominations are popular and tend not to be aggressive. Another way is to ask children directly to identify who is popular or ask them to rate their own popularity (referred to as *perceived popularity*). There is a positive correlation between perceived popularity ratings and aggression (Cillessen & Rose, 2005).

and social demonstration-approach) and a negative association between perceived social competence and a social demonstration-avoid goal (see Elliot, 2005, for a review of other domains). Further, on the basis of research in social development, we expect that perceived social competence will be related to social adjustment (Harter, 1982; Ladd & Price, 1986; Robins & Pals, 2002; Wheeler & Ladd, 1982). Thus, perceived social competence is intimately related to the central constructs of this investigation. To fully understand the role of social achievement goals for social adjustment, we consider them in tandem with perceived social competence to investigate unique and possibly interactive effects. First, we examine social achievement goals and perceptions of social competence simultaneously as predictors of social adjustment in our regression analyses. We expect social achievement goals to predict social adjustment above and beyond perceptions of social competence. Such unique effects for achievement goals and perceived competence have been established in other domains (see Elliot, 2005, for a review) but have not been examined in the social domain. To support our contention that social achievement goals are important to social adjustment, it is important to show that they predict social adjustment above and beyond omnibus perceptions of social competence.

Second, we examine possible interactive effects between perceived social competence and social demonstration goals. Focusing on the judgments of others may have different implications depending on how confident someone is in his or her abilities. Although theory and evidence are mixed, this issue has been the source of much attention in the academic domain (Dweck & Leggett, 1988; Elliot & Church, 1997; Elliott & Dweck, 1988; Harackiewicz & Elliot, 1993; Smiley & Dweck, 1994). Dweck and Leggett's (1988) view is that perceived competence moderates the effects of demonstration goals (analogous to performance goals in the academic domain). Specifically, it is only when perceived competence is low that demonstration goals are associated with maladaptive outcomes (Dweck & Leggett, 1988). Dweck and colleagues' studies with children have found evidence for this view of perceived competence as a moderator (e.g., Elliott & Dweck, 1988; Smiley & Dweck, 1994). Elliot views perceived competence as related to achievement goals but does not view it as a moderator. Elliot and colleagues' research with college students consistently documents support for his view (e.g., Elliot & Church, 1997; Harackiewicz & Elliot, 1993). Thus, we examine whether perceived social competence moderates the relation of social demonstration goals to social adjustment.

### Interactive Effects Among Social Achievement Goals and by Gender

Although they are not the main focus of the present research, we explore two other types of interactive effects that have received attention in achievement goal theory and research. First, we examine whether gender moderates the effects of achievement goals on social adjustment (see Midgley, Kaplan, & Middleton, 2001). This is important because there is some research that suggests that achievement goals may have different implications for boys and girls, particularly performance goals (analogous to demonstration goals; e.g., Bouffard, Boisvet, Vezeau, & Larouche, 1995; Urdan, 1997). Much extant achievement goal research has not examined such gender by achievement goal interactions, so the extent of such

gender differences is not known. Second, we examine interactive effects among achievement goals. This is important because students may pursue multiple goals, and the effects of one goal may be different when pursued in conjunction with another goal (see Barron & Harackiewicz, 2001). The evidence for interactive effects among achievement goals is inconsistent, but again, many researchers have not examined interactions, which hinders definitive conclusions (Barron & Harackiewicz, 2001; Midgley et al., 2001). Of the three studies concerning social achievement goals in college students, one study examined potential interactions and few were found (Ryan & Shim, 2006). We make no hypotheses, but explore these types of interactions among social achievement goals in young adolescents to ensure we are not missing important patterns by focusing only on main effects. This is particularly important as we expand achievement goal theory into a new domain.

## Summary of the Present Research

In summary, we designed the present research to investigate the extension of an achievement goal framework to the social domain for young adolescents. In Study 1, we collected open-ended data on young adolescents' descriptions of social goals and social competence. In Study 2, we created new survey items to assess young adolescents' social achievement goals. We assessed the structure and nature of the new measure with factor analyses and examined the hypothesized relations of students' social achievement goals to their subsequent social adjustment (assessed with teacher and self reports).

### Study 1

In Study 1 we sought to establish that an achievement goal perspective is relevant and applicable to the social domain for young adolescent students. We used open-ended questions to elicit descriptions of social strivings from young adolescents. We used three different open-ended questions with subgroups within our sample, such that each child only responded to one question. The use of different questions bolsters confidence that results reflect an accurate portrayal of young adolescents' social strivings and are not an artifact produced by the use of a particular term or phrase in the question. The use of brief open-ended responses from a large and diverse sample of young adolescents (as opposed to lengthier interview responses from a much smaller number of students) increases confidence that results are actually representative and salient in young adolescents' social strivings. Showing that different orientations to social competence can be seen when students write a sentence or two will be convincing evidence that an achievement goal approach is relevant and potentially important to young adolescents' social adjustment.

### Method

#### Participants

The participants were sixth-grade students from two public middle schools. The schools serve nonmetropolitan, small urban communities and report that about half of their students are eligible

for free or reduced-price lunch.<sup>3</sup> At each school, we asked the principals to choose a few representative classrooms to participate in the research. Letters describing the project were sent home with all children in those classrooms, and 80% of the students returned a slip with their parents' written consent for them to participate. The sample ( $N = 153$ ) was 49% female and ethnically diverse (43% White, 35% Black, 8% Asian, 5% Hispanic, 3% Asian Indian, and 7% other).

### Procedure

Trained researchers distributed questionnaires to students in their classrooms. Teachers remained in the classrooms. The questions were read aloud, and then students were given time to write their response. Students were told there were no right or wrong answers and that the purpose of the questionnaire was to find out students' thoughts at school. Students were assured that the information would be kept confidential. In addition, students were told that answering the questions was voluntary; if at any point they wanted to stop, they could do so.

### Measures

Students responded to one of three different versions of the open-ended questions. Thirty-five students responded to Question 1 (Q1), which was, "What are your social goals for this year in school? Please elaborate why these goals are important to you." Sixty-one students responded to Question 2 (Q2), which had two parts. Part A was, "If you were a social success this year in sixth grade what would this look like? Please elaborate why you would feel like a success." Part B was, "If you were a social failure this year in sixth grade what would this look like? Please elaborate why you would feel like a failure." Fifty-seven students responded to Question 3 (Q3), which was, "Sometimes kids feel good about how they get along with other kids at school. Other times kids do not feel good about how they get along with other kids at school. Think about how you are with other kids at school. Now think about the rest of the school year. What are your goals for getting along with other kids at school? Please elaborate why these goals are important to you." For all three questions, students were told that by "social" we meant how you get along with other kids at school—friendships and social life in general at school. These three questions were developed from eight half-hour interviews with sixth-grade students (not part of the present sample).

### Results

All responses were coded independently by two coders. Students generally wrote one to two sentences below their question. We treated all information from each student as one response (thus, we had 153 distinct responses). Coding proceeded in two phases. First, we coded for evidence of development versus demonstration. Second, we coded for approach or avoid valence. Our conceptual framework did not concern a development-avoid goal because, in part, we assumed it would be less prevalent; by coding for this goal in the open-ended data, we could examine the assumption.

### Development Versus Demonstration

In Phase 1, we assigned each student response one of three codes: *development* (evidence of development only), *demonstration*

(evidence of demonstration only), or *neither* (response concerned social strivings but there was no evidence for either social achievement goal). Initially, we also included a category for a response that contained evidence of both development and demonstration goals, but there were few students in this category—5% overall, 2 (6%) for Q1, 2 (3%) for Q2, and 4 (7%) for Q3. As the aim of the study was to provide evidence that social achievement goals were relevant to social strivings in general (not to compare configurations in individuals), this category was dropped. Instead, if a student response contained reference to both social development and demonstration goals, it was double coded (about 5% of students had responses that were double coded). Fifteen students wrote responses that contained no reference to the social domain and thus were considered missing data and removed from the coding process (15 overall; 10, 0, and 5, for Q1, Q2, and Q3, respectively; sample numbers reflect final numbers of students with valid data). Reliability between coders was 90% ( $\kappa = .85$ ,  $p < .001$ ; Cohen, 1960). Disagreements were resolved through discussion.

A response was coded as social development if it concerned a focus on developing social competence. To be coded as evidence of a social development goal, comments needed to go beyond achieving a certain outcome and make explicit reference to improvement. Thus, comments such as "develop better friendships," "be more friendly," and "be less selfish" were considered evidence for a social development goal, whereas comments such as "make friends," "be nice," or "have fun" were not (and thus were coded as "neither achievement goal"). A response was coded as evidence for a social demonstration goal if it concerned a focus on others' judgments of social competence and how one looked in front of others. Thus, comments such as "I would be seen as having lots of friends" and "Many people would like me" were considered evidence of a social demonstration goal because they explicitly refer to others' impressions, whereas comments such as "I would have lots of friends" were not. Further, comments such as "I would be popular," "I would be cool," "I would have popular friends," or "I would have cool friends" were coded as a social demonstration goal because use of the terms popular or cool connotes a focus on social recognition from others and a concern with high social status or a social standing that is better than others (i.e., the nonpopular or uncool people). Examples of social development and demonstration goals for each of the three questions are shown in Table 1.

Table 2 shows the percentages for the different codes. Across all three questions, 70 of the students (46%) made reference to social development goals, 54 students (35%) made reference to social demonstration goals, and 40 students (26%) gave responses that did not contain strong evidence for either social development or social demonstration goals. There were some differences in the results by question. Q2 garnered more demonstration than development responses, whereas Q1 and Q3 garnered more development than demonstration responses. However, both types of ori-

<sup>3</sup> These schools do not separate students by gifted or special education status. In both Studies 1 and 2, a few special education students were excluded because their teacher judged the research inappropriate for their skill level.

Table 1  
*Examples of Social Development and Social Demonstration Achievement Goals From Open-Ended Data*

Open-ended questions	Social development goal	Social demonstration goal
What are your social goals for the upcoming year? Please elaborate why these goals are important to you.	I want to grow my friendships with my friends. Be kinder than I am now. Be a better friend. Know my friends better.	Be popular so when I walk in the hallway everybody knows my name. Not be picked on. I don't want to be made fun of
If you were socially successful next year what would this look like? Please elaborate why you would feel like a success.	I would be nicer to others. I made friends and learned more about people. If I made new friends... learn to open up when I need to and I will know when to stop.	Everyone will talk to you. You would feel like the center of attention all the time. A lot of people would know me... People would recognize me when I walked through the hallway. I would be cool... feel like a success because I was popular and a cool kid, not one of those nerds. I had a new girl friend and made tons of new friends and sat at the popular table.
If you were a social failure next year what would this look like? Please elaborate why you would feel like a failure.	I would feel lonely and without any friends... I would feel like I didn't do my best. I would not care about anyone but myself and not let people get to know me or get to know other people. I would have no one I could trust and I would be letting myself down.	I would be a social outcast, little or nobody would like me. I'd feel like a loser, not popular. I would have no friends, be at the bottom of the social pyramid. People would laugh at me.
Sometimes kids feel good about how they get along with other kids at school. Other times kids do NOT feel good about how they get along with other kids at school. Think about how you are with other kids at school. Now think about the rest of the school year. What are your goals for getting along with other kids at school?	Be funnier. Be more open so I can learn about others. Become a better friend to others. Act in better/kinder ways for my friends. Learn more about all my friends. Be less selfish. Try to get along with Warren better. We've been friends for 3 years but he can still go into flurries of rage sometimes.	Get Jessie Rubins to like me... she's rather popular. I want to have a good reputation. Get respect. Not have no one like me. Become more popular. Not be picked on by others... be recognized by others.

*Note.* Students were told that by "social" we meant social skills, social relationships, and social life in general.

entation to social competence could be seen in responses to all three questions.

### *Approach Versus Avoid*

In phase two of the coding, each coded response for Q1 and Q3 was then coded for approach-avoid valence. Q2 was not coded for approach-avoid valence because we had explicitly asked students to describe success (approach goal) and failure (avoid goal). We assigned each student response to Q1 and Q3 one of four codes: approach (striving to achieve a positive outcome), avoid (striving

to avoid a negative outcome), both (containing both approach and avoid goal statements), or neutral (desiring to stay the same and vague about whether this would be continuing to accomplish a positive outcome or continuing to avoid a negative outcome). For example, "be more generous" would be coded as approach, "be less selfish" would be coded as avoid, and "stay the same" would be coded as neutral. For the 55 responses that had been coded as having evidence of a social development goal in Q1 and Q3, 65% (38) were approach, 15% (8) were avoid, 13% (7) contained both, and 7% (4) were neutral. For the 21 responses that were coded as having evidence of a social demonstration goal in Q1 and Q3, 48%

Table 2  
*Open-Ended Responses Coded as Evidence of Development, Demonstration, or Neither Social Achievement Goal*

Goal	Question 1 (n = 35)		Question 2 (n = 61)		Question 3 (n = 57)		Total (N = 153)	
	Response	%	Response	%	Response	%	Response	%
Development	20	57	15	25	35	61	70	46
Demonstration	6	17	33	54	15	26	54	35
Neither	11	31	17	28	12	21	40	26

*Note.* Percentages do not add to 100% because some students' responses made reference to both development and demonstration goals and thus were double coded.

(10) were approach, 24% (5) were avoid, 29% (6) contained both, and 0% were neutral. Across questions, reliability between coders was 100% (number of agreements/number of possible agreements).

### Discussion
